Preface

This is the third edition of the *Manual of Child Psychology*. The first and second editions, edited by Leonard Carmichael, were published in 1946 and 1954 respectively. It should be clear from the outset, however, that the present volumes are not, in any real sense, a *revision* of the earlier editions, this is a completely new *Manual*.

The general purpose of this edition, like that of the previous ones, is to provide a comprehensive and accurate picture of the current state of knowledge—the major systematic thinking and research—in the most important research areas of the psychology of human development. But developmental psychology has been radically transformed, in numerous and complex ways, in the last two decades. While some features of the discipline—its goals, approaches, and research foci—have not changed much, its overall “look” in 1970 is vastly different from what it was in 1950. Complete specifications and analyses of all the changes, which are intimately connected with one another, and of the reasons for them, would require a long essay on the history of the field and the social forces that shaped it. However, a brief survey of some of the enduring characteristics and major shifts may help to provide a broader perspective and to clarify the contrasts between the 1954 edition and the present one.

Many crucial contemporary problems were apparent even in antiquity and have recurred repeatedly throughout the history of developmental psychology; however, they remain unresolved and continue to be the impetus for much research. An example is the problem of whether the individual's development and attainments are primarily determined by his genetic makeup or by environmental condi-

tions, by nature or by nurture? Generally speaking, the basic objectives or tasks of present-day developmental psychology, which are interrelated, are the same ones that characterized the field 20 years ago—description of the genesis of behavior and of age changes; explanation of these (the mechanisms, processes, and determinants of change); delineation of the relationships between early and later behavior. But the distribution of scientific resources and publications devoted to the various goals has changed markedly. Until approximately 25 years ago, developmental psychologists were primarily concerned with precise descriptions of children's capabilities at various ages and reliable determination of age changes in psychological functions such as psychomotor performance, problem solving, and aggressive reactions. And there are continuing needs for more accurate, detailed descriptions of the transformations, continuities, stages, and discontinuities in many aspects of development, particularly in cognitive functions and in social and emotional behavior.

The major contemporary empirical and theoretical emphases in the field of developmental psychology, however, seem to be on *explanations* of the psychological changes that occur, the mechanisms and processes accounting for growth and development. Hypotheses dealing with the beginnings of behavior, and with the determinants of change have been tested experimentally and in naturalistic settings. Investigations of factors correlated with individual differences in psychological functions, traits, and abilities as well as longitudinal research, also yield valuable data bearing on the problems of stability and continuities in development and the mechanisms of change. Compared with the

last edition, this one includes many more accounts of studies of these kinds.

Increased interest in mechanisms of change stimulated more theory-building and, consequently, theory seems to be generally more prominent in the literature of developmental psychology today than it was in 1950, often playing a much more critical role in determining the direction of empirical research. This is particularly true in the area of cognitive development, where the theories of Piaget and of Werner have been major sources of research hypotheses and further conceptualizations relating to the nature of perception, thought, and problem solving.

The 1954 edition of this *Manual* had only one theoretical chapter and that was concerned with Levinian theory which, so far as we can see, has not had a significant lasting impact on developmental psychology. Volume I of the present edition includes four chapters exclusively devoted to theory and, in addition, relevant theoretical issues are discussed in some detail in most of the substantive chapters. Psychoanalytic theory is probably not as powerful an intellectual force in child psychology today as it was 20 years ago but it is still important in stimulating and guiding research in personality and social development. Unfortunately, the chapter on psychoanalysis as a developmental theory, originally planned for this edition, was not completed. However, a number of chapters in this volume discuss aspects of this theory and two recent books offer excellent discussions and critiques of psychoanalytic developmental theory.¹

Like all scientific fields, developmental psychology has experienced its own "knowledge explosion." The sheer number of relevant articles and books has increased, and continues to increase, at an awe-inspiring rate, and the newer literature is broader in scope and more varied in content than that of 20 years ago. Theoretical and empirical analyses of fundamental problems have become more penetrating, refined, and sophisticated. At the same time, the invention of ingenious new methods and techniques of investigation in

developmental psychology and related fields, together with modifications and improvements in older ones, paved the way for more adequate, reliable, and meaningful research into complex problems of long standing (or variations of these) and into more recently formulated questions. As a result of these advances, many new facts have been accumulated and many previously "accepted" findings have been reconsidered and discarded. Some established theories have been revised and abandoned while alternative theoretical approaches have been proposed and systematized. Whole areas of research and theory such as behavior genetics, ethology, and large segments of developmental physiology, hardly existed 20 years ago but, by 1970, they have achieved scientific maturity and contribute substantially to the field of developmental psychology. Largely because of this kind of knowledge explosion and its consequences, this edition of the *Manual* is in two volumes, rather than the one-volume previous edition, and has twice as many pages.

Recent social and historical events have also generated more active concern with the potential practical contributions of the systematic study of developmental psychology. Responding to critical social needs, many developmental and educational psychologists have turned their research attention to applied problems such as promoting cognitive abilities, improving teaching techniques, raising the educational and intellectual status of the culturally disadvantaged, understanding the etiology and treatment of mental retardation and psychopathology, and preventing juvenile delinquency. The findings of empirical investigations in these problem areas have both practical and theoretical significance, as several of the chapters in this volume demonstrate (See, for example, the chapters in Volumes I and II on early experience, creativity, implications of cognitive development for education, social class and ethnic group influences on socialization, moral values and behavior, mental retardation, behavior disorders, and psychosis in childhood.)

Inevitably, the knowledge explosion and the continuous, if modest, advance in theory and application in developmental psychology have resulted in greater specialization within the field. The organization of the present volume and the contents of the chapters are

¹ See Baldwin, Alfred L., *Theories of child development*. New York: Wiley, 1967, and Langer, Jonas, *Theories of development*. New York: Holt, Rinehart, and Winston, 1969.

testimony of this. While the 1954 edition of the *Manual* had only one chapter on emotional development and another on social psychology, Volume I of the present edition has a major section on socialization, consisting of seven chapters. These deal with the following topics: sex typing and identification, affiliative behavior and dependency, aggression, moral values and behavior, peer interaction, and social organization. Two chapters of the second edition were devoted to mental growth and development, and one dealt with psychopathology. The present edition contains ten chapters on cognitive development (Volume I), and three on abnormal behavior in children (Volume II).

The enormous growth in quantity of relevant literature, the high degree of specialization, and the changing tone of developmental psychology make it exceedingly difficult to produce a full, balanced, accurate, and up-to-date representation of the state of the discipline. In trying to achieve this, I was most fortunate to have the help of five distinguished developmental psychologists who served as an Advisory Committee: Professors Jerome Kagan of Harvard University, William Kessen of Yale University, Eleanor Maccoby of Stanford University, Harold Stevenson of the University of Minnesota, and Sheldon White of Harvard University. We worked together in every phase of planning and organizing this *Manual*, from original conceptualization to final editing.

As we conceived it, the *Manual* is a comprehensive textbook or sourcebook for advanced undergraduate and graduate students as well as for specialists in many areas of psychology and in related fields such as ed-

ucation, psychiatry, and pediatrics. Hence, it must represent, as far as possible and in abbreviated form, all the established and influential theories, as well as the reliable accumulated knowledge, in developmental psychology. But it should not consist simply of organized summaries of the literature. Instead, great stress should be given to critical analyses and evaluations; major gaps in theory and data should be illuminated. In brief, the *Manual* should foster the development of new perspectives and insights and, ultimately, it may stimulate some readers to formulate hypotheses and to conduct research.

With this in mind, we made many difficult, critical decisions about the table of contents, essentially pooling our judgments about the areas that are currently most productive of theory and investigation. Obviously, specialized areas of interest could not be fully covered. We collaborated in selecting and inviting recognized authorities who could write stimulating, comprehensive, and integrated chapters, and fortunately, almost all our invitations were enthusiastically accepted. Every "working outline" and final manuscript was reviewed by the editor and at least one member of the Advisory Committee who made suggestions for revisions.

Without the diligent and painstaking work of the authors and the invaluable assistance of the members of the Advisory Committee, this book could not have been completed. I gratefully acknowledge my vast indebtedness to all of them. Whatever success these volumes achieve is due as much to their efforts as to my own.

**BIOLOGICAL BASIS
OF DEVELOPMENT**

1. Ethology and Developmental Psychology

ECKHARD H. HESS

Man is an animal. He is a biological organism with an evolutionary history. Nevertheless, when it is suggested that, in common with other animals, man may manifest inherited, or genetically programmed behaviors, dissent often comes quickly from behavioral scientists. Indeed, it is unfashionable these days to investigate such genetically determined behavior in humans. For example, Spuhler and Lindzey (1967) complete a recent summary of human behavior genetics with respect to possible racial differences by stating that it is "an area of research that is procedurally difficult, politically dangerous, and personally repugnant to most psychologists, sociologists, and anthropologists."

If we look at the behavior of *all* animals on this earth we reach three inescapable conclusions.

1. Innate behavior is the necessary and *sufficient* condition for the survival of most organisms.

2. Learned behavior, alone, is the necessary and *sufficient* condition for the survival of none. Those few organisms most interesting to us, as psychologists, undoubtedly are heavily influenced by learning. This, however, does not alter the truth of these two conclusions.

3. Innate, or genetically programmed behavior is necessary for the survival of *all* animals.

Even the effectiveness of learning or conditioning has to depend on the genetically determined *positive* or *negative* value of whatever reinforcement takes place. Reward and punishment are meaningless concepts when used without reference to the condi-

tions that make them work. These conditions must already be present, that is, innately possessed, or else they must be built up by environmental or learning processes which ultimately *rest on some innate response*. In other words, learning cannot be shaped by reward or punishment unless the organism is already structured so that reward and punishment *will* have positive and negative values, respectively: the survival value of specific consequences of behavior has, through the course of evolution, formed organisms that are innately constituted to act to attain reward and to avoid punishment. The "consummatory acts" of learning experiments are innately fixed behavior patterns which serve to reinforce preceding behavior acts. It is particularly in the human infant that we have an opportunity to observe behaviors that *must be there* for the infant to survive. Learning cannot come along quickly enough to assure its survival.

We shall not enter into the argument regarding the "usefulness" of distinguishing between innate and learned behavior, which has been brought up by numerous psychologists. "Innate behavior" is used here to mean genetically programmed behavior, just as we have genetically programmed morphology. Morphology, as is well known, is based upon genetically stored information possessed by the species and the individual. The sequential development of the body form during ontogeny, beginning with fertilization and following through to the mature shape, is programmed by this genetic information. Innate behavior is programmed in the same way, and in this sense specific innate behaviors may be regarded as individual organs

possessed by the organism (Lorenz, 1937). Beginning with the section on Innate Behavior we shall discuss how ethologists have utilized this concept.

"Learning" here refers to what the learning psychologists call learning. Miller (1967) has listed a set of criteria for determining instances of learning. Environmental components such as temperature, oxygen, and water are excluded from learning. Such components can have an effect on behavior, just as they can have an effect on morphology, and thus they should be regarded as factors that can alter the expression of genetic potential rather than as learning.

With this frame of reference, then, let us turn to a description of the ethological approach to the study of behavior and to the concepts and theoretical viewpoints characteristic of most of those scientists who can be called "ethologists."

BASIC CONCEPTS IN ETHOLOGY

The Ethological Approach to the Study of Behavior

Behavior is so multiform that innumerable theories have been developed in the attempt to explain it on the basis of partial knowledge. Indeed, the facets of behavior are such that it is possible to glean supporting evidence for any theory of behavior, even one that is capriciously constructed. The fable of the blind men and the elephant is completely applicable to this situation: theories of behavior are usually extrapolations based upon only some segment of all the behavioral phenomena that exist.

Recently the discipline of ethology has gained increasing attention from students of behavior, principally because ethologists have taken theoretical positions very different from those maintained by traditional behavioristic theories, which sought principally to examine the influence of the environment upon behavior. However, the theoretical positions of ethologists are not their only distinguishing characteristics, for the very data that they gather are also different.

It must be said, nevertheless, that the ethologists' theory does not determine what kind of facts they search for and which ones they will discard. Rather, it is the philosophy of ethologists that facts come first; after they

have been gathered, a theory to accommodate *all* facts may be attempted. Any theories so constructed are limited to the particular set of facts upon which they were founded. And ethologists tend to have an almost compulsive passion for collecting *all* the facts.

Even so, the facts that ethologists initially collect are those of a particular universe. This is because ethology has as its major premise the notion that the study of behavior begins through the compilation of as complete an inventory as possible of all the behaviors of the organisms in, and in relation to, its natural environment, throughout its entire life cycle. A collection of such observations on a single species is called an "ethogram." An ethogram is purely descriptive, cataloguing as exhaustively as possible what an animal does without any concurrent concern regarding the causal bases of such behavior. However, ethograms do go beyond the usual naturalistic approach because the behaviors are then classified and compared with those of many other species, particularly related ones.

Ethology first developed from the work of zoologists, who were interested in the study of the natural behavior of animals. Faced with the mass of facts they had garnered, these zoologists soon saw several conceptual similarities between morphology and innate behavior. In fact, modern ethology really began with the discovery of the taxonomic value of the innate behaviors known as fixed action patterns (Hemroth, 1910, Whitman, 1898). Today we can see a rather thorough application of concepts derived from morphology, evolution, and embryology to the analysis of innate behavior.

From the outset ethologists have emphasized the importance of the natural behavior of animals in their own habitats as the fundamental basis upon which any subsequent analysis of behavior must build before formulating any hypotheses regarding behavior. This initial approach was intended as a corrective to an earlier, prevailing tendency of environmentally oriented animal psychologists to confine their attention to a limited number of phenomena observed in a few species maintained in impoverished and artificial laboratory surroundings since birth. Such circumscribed and unnatural observations nevertheless led these psychologists to formulate extremely wide-ranging theories, which pro-

posed to encompass all behavior phenomena, even those in man.

The importance of the natural environment in studying the behavior of animals has been emphasized because it is much more difficult to maintain animals in an optimum state of health in conditions of captivity. Captivity may thus result in the failure of animals to manifest some aspects of their behavior capabilities. In addition, captive animals frequently engage in abnormal stereotyped behaviors, as is evident to most zoo-goers.

There is an intimate relationship between the behavior of animals and the characteristics of their wild habitat, according to ethologists. Certainly it is obvious that there is a relationship between what an animal needs, in the way of shelter or food, for example, the environment in which these are naturally found, and the animal's behavior in relation to that environment. Unlike laboratory conditions, which place restrictions and artificial conditions on the animal, the animal's behavior in the wild significantly fits the natural environment.

The ethologists have concentrated initially on naturally occurring behavior rather than solely on learning processes, as many animal psychologists have done. It is their conviction that the basic material already present in an animal must be known before changes in this substratum through learning or any unusual environmental exposure can be studied. This emphasis has led some psychologists to mistakenly assume that ethologists do not regard learning as very important. On the contrary, they regard learning as of the highest importance, and as one of the many mechanisms that produce behavior in animals. They do not hold the belief that a given behavior is either wholly learned or wholly innate—only the basic components or units are one or the other; this aspect of ethological theory will be discussed later.

Although the starting point is always the collection of ethograms, the ethologists naturally go much farther than this. Subsequent to the cataloguing of the animal's behavior into an ethogram is the analysis of the behaviors with respect to the factors that enter into or influence the behaviors. At this point it is considered permissible to change the environment experimentally because we can then know with greater certainty in what ways

these changes influence the animal's behavior. Deprivation experiments, in which animals are deprived of certain environmental factors such as social experience, auditory experience, or visual experience, constitute a technique as familiar to the ethologists as to animal psychologists.

Consonant with their biological training, the ethologists not only study animal behaviors with respect to environmental factors but also attempt to assay their probable evolution, ontogenetic development, survival value or function, and physiological bases. All of these are extremely important aspects of present-day ethological theory and research.

Innate Behavior

Early workers such as the German zoologist Baron von Perna (1707), the French naturalist Réaumur (1734–1742), Charles Darwin (1872), the English naturalist Spalding (1873), and later the American zoologists Jennings (1904), Craig (1918), and Whitman (1898), and the German zoologist von Uexküll (1909) had all studied unlearned behavior in animals scientifically. But the blatantly promiscuous use of the term "instinct" during the late nineteenth and early twentieth centuries by many psychologists in the United States and elsewhere had reduced it to a catch-all explanation for behaviors which were not readily understood. The reaction to this inappropriate use of the term was like "throwing out the baby with the bath water," for the concept of instinct or innate behavior was completely denied by psychologists who were attracted to Watson's (1922, 1928) behavioristic theory, which promised to explain behavior on the basis of simple relationships between the individual and his environment.

The work of the ethologists has provided a substantial scientific and renewed theoretical basis for the use of the concept of innate behavior. The ethological concept of innate behavior is that it is relatively complex animal activity, which generally involves the whole organism rather than merely an isolated part. Such behavior is a characteristic of the species to which the animal belongs rather than of the individual, whereas learned behavior is *individually* acquired during ontogeny. Since the behavior is a species characteristic, it originates without previous experience or modification caused by experience: it is genetically

programmed, as are many morphological features. Environmental factors, of course, can alter the expressions of innate behavior or morphology. Inheritance, or phylogenetic adaptation of the species recorded in the genome (set of chromosomes with constituent genes), is considered the ultimate criterion of innate behavior. Stereotypy is not the criterion of innate behavior, since it can also occur in many individually acquired learned behaviors. Furthermore, innate behavior has an end or purpose, but many experiments have shown that the animal does not perform the behavior for this purpose. To cite only one example, prey hunting by dogs and cats that are well fed is performed for its own sake. In other words, the animal appears to need to perform the movements involved in hunting, and not solely for the purpose of obtaining food, although the fact that under wild conditions such behavior does have this utility indicates the survival value which tends to preserve this behavior in the species. Finally, species-specific behavior is itself composed of several elements: reflexes, taxes (directed orientations), and fixed action patterns.

Ethologists maintain that it is sometimes difficult to distinguish between innate behavior and behavior learned early in the life of the animal because there are some innate behaviors that are not apparent until after certain developmental stages in the life cycle have been achieved. This is the problem of ontogeny, which sometimes still presents an impasse between most ethologically oriented researchers and certain animal psychologists. Just as did Erasmus Darwin (1794) or Kuo (1932a-d), the latter proposed that the presence of a given behavior at the moment of birth could mean that it was *learned before birth*, whereas ethological researchers were vigorous proponents of the view that innate behaviors could be regarded as possessed by animals as are organs or other morphological features. Furthermore, the ethologists pointed out that there are morphological features that are not present at birth.

Charles Darwin (1883) viewed innate behaviors as being just as subject to modification by natural selection as are morphological characters. In fact, Darwin applied exactly the same principles of morphological evolution—convergent, divergent evolution, natural selection pressure, and variation between in-

dividuals—to the evolution of innate behavior. Before Darwin it had been generally believed that the “knowledge” animals displayed in their innate behavior was implanted in them by the Creator. With Darwin’s theory came the notion of the transmission of such innate behavior from one generation to another through heredity, evolving in response to the forces of natural selection. The evolutionary view of behavior was supported and expanded on by Spalding (1873), Morgan (1896), Wesley Mills (1896), Romanes (1881, 1883), Whitman (1898), Thorndike (1899), and Henroth (1910).

The biological and evolutionary viewpoint on innate behavior remains the bulwark of ethological philosophy and theory. A recent definition of innate behavior by an ethologically oriented neurophysiologist, for example, is: “actions of an individual animal that are inevitable expressions of a neural organization determined and unfolded in ontogenesis in the same way as is the body form characteristic of the species” (Roeder, 1963). The genotype, according to Roeder, expresses itself in the entire morphological make-up of the individual organisms, including the nervous system down to fine details of sense organs, nerves, and neuronal connections. Innate behavior is regarded as the expression of this neural organization.

Today many psychologists in the United States have what is called an “epigenetic” view toward behavior; the main proponents of this view are Schneirla (1946, 1956, 1957, also Schneirla and Rosenblatt, 1961), Hebb (1953), Lehrman (1953, 1956), and Moltz (1965). The epigenetic viewpoint, according to Moltz (1965), “considers gene effects as capable of entering into different classes of relationships depending on the prevailing complex.” Essentially, this epigenetic viewpoint appears to be one that arose out of the growing conviction that the traditional heredity-environment dualism served only to obscure the problem of the origin of behavior. This viewpoint apparently has its roots as long ago as 1925 when Carmichael pointed out that it was not possible on the basis of the then-current knowledge to differentiate between that which is native and that which is acquired, once the fertilized egg has begun to develop. “The so-called hereditary factors can only be acquired in response to the environ-

ment and likewise the so-called acquired factors can only be secured by a modification of already existing structure, which in the last analysis is hereditary structure," Carmichael (1925) declared.

Thus it is that psychologists such as Schneirla (1946, 1956) have postulated that species-typical behaviors do exist, while denying that there are separate (and/or unitary) entities such as learning or instinct, which produce behavior. Learned behavior and innate behavior, although usually regarded as distinct by many ethologists, are not necessarily antithetical, as we shall soon see.

The Functions of Innate Behavior

Although ethologists use the terms innate and learned, they do not conceive of two parallel, independent neural mechanisms determining behavior. Learning processes may possibly constitute a natural unit, from the ethological point of view, and they may possibly have similar physiological processes in common with each other. But it is an error to think that ethologists postulate only *one* neural behavior-determining process into which learning does not enter. Rather, they say that *many* physiological processes innately determine behavior and that these processes are as different from each other as they are from learning. Not only do they have different origins, but they also are completely distinct from each other in their functions. Such mechanisms as the "innate releaser mechanism," "fixed action pattern," "orientation reactions," and "optomotoric reactions" are examples. Their only common property, according to the ethologists, is a negative one: the lack of learning processes, a criterion as useless as the lack of dental enamel in an anatomic group composed of knees, hands, and nose. All of the preceding behavior mechanisms, both learning processes and innately based behavior processes, are considered distinct rather than antithetical. Basic components or units of behavior rather than entire behaviors are determined by one or another of these mechanisms, so that any instance of gross behavior may be seen to consist of a unit-by-unit *intercalation* (interpolation or interweaving) of learned and various innate behavior mechanisms, an important concept which shall be discussed shortly.

One of the overriding interests of the ethologists in the analysis of behavior is the con-

sideration of its *survival value* (defined as utility in the struggle for existence). In some cases the survival value of a behavior is so apparent that it hardly requires experimental investigation, (e.g., incubation behavior in broody hens), yet there are several other cases where this is far from true, and with these instances considerable study and analysis are required to elucidate their survival value. As Tinbergen (1963) pointed out, why do certain cryptic insects (those that escape predation by resembling leaves, bark, or twigs) perform rocking movements? Movement is a stimulus to which predators commonly react. Nevertheless, the rocking movement occurs in a large number of cryptic animals, which indicates that this movement has a survival value that is in some way related to camouflage.

The difficulty in immediately ascertaining survival value also exists with respect to morphological and certainly physiological features. As an example consider man's unfurred skin in stark contrast to the abundant fur of all other primates. Because any given behavior or bodily character has been subjected to the forces of evolution, it has therefore served as a means for survival, either in the past or at present. It does not, of course, necessarily have the most survival value for the particular animal in comparison with other alternatives. This is illustrated by the fact that male argus pheasants possess tremendous feathers, which have the function of sexually attracting the female. However, these feathers are detrimental to escape from predators, and thus conflict with that survival need. Nevertheless, the attendant survival value of their sexual attractiveness is such that the argus pheasant does not evolve shorter feathers in the male (Lorenz, 1966).

Although the past evolution of a species' behavior cannot be subjected to experimental proof and must be traced by indirect means, ethologists maintain that it is certainly possible in many cases to examine the question of how the present-day behavior of animals serves to promote survival. The fact that animals do survive in their natural environment is a problem that is related to every detail of behavior and structure, no matter how self-evident or insignificant it may seem to be. For example, as Tinbergen (1963) stated, there are adaptive reasons for the differences in

the walking behavior of the godwit and the lapwing, as Klompf (1954) has shown. Godwits lift and fold their feet much more than do lapwings and thus avoid getting their toes caught in the tall grass in which they breed. Lapwings, however, avoid habitats with tall vegetation. Tinbergen (1963) has demonstrated that the question of the survival value of behavior is in itself a vast field for experimental study that has great potential.

Regardless of whether a behavior is a learned or a phenotypic expression, its ultimate value is, as we have stressed, assumed to be in the service of the survival of the individual or species. Learned behavior aids in the survival of the individual only, whereas other behavior mechanisms insure the survival of the species. Lorenz (1961, 1965) has developed a theoretical position with this notion at its core. He maintains that there are really two and only two entirely independent (but not antithetical) mechanisms that effect the *adaptation* of behavior. If an organism shows adaptive behavior, this means that it has been molded to fit the environment in a way that will achieve survival, according to Lorenz, there are only two ways in which this molding may be achieved. The first is the process of phylogeny, which evolves behavior mechanisms just as much as any morphological feature or physiological function. The second is the process of ontogeny, which involves adaptive modification of behavior during the individual's life. Lorenz has emphasized that although mutation and individual learning, are two entirely distinct processes, both have the very important function of creating and/or adaptively changing the structure of the neural apparatus determining behavior. In fact, Lorenz's position goes to the extent of postulating that there is selection for learning ability during the process of phylogeny, and this ability has been fixated in the genetic constitution of the species. The increase in survival value effected by learning processes is, in Lorenz's opinion, the ultimate proof that learning processes in themselves are the product of adaptive evolution.

Therefore, Lorenz deduced, learning is a *specific* survival-achieving function of the organism. Modifiability of behavior through learning processes, he suggested, occurs at specific, evolutionally preformed places where inbuilt learning mechanisms wait to perform

just that function. Very often these inbuilt learning mechanisms are unable to modify any but *one* very circumscribed system of behavior mechanisms. For example, Lorenz points out, honeybees can use irregular forms such as trees and rocks as landmarks to find their way to the hive. But they are unable to use these forms as signals indicating the presence or absence of food. The types of forms that bees *can* learn to use as food signals are those that are geometrically regular, preferably radially symmetrical.

Examples of coexistent learned and innate components in behavior are numerous in ethological literature. It has been observed in many bird species that innate nest-building movements may be made but the individuals must learn which materials to use for this purpose. Eibl-Eibesfeldt (1956a) has shown that in the prey-killing technique of the polecat, the killing bite, that is, the sinking of the teeth into the animal and shaking at the same time, is innate, whereas the directing of the killing bite to the prey's neck is learned in a few trials. Eibl-Eibesfeldt (1956b) also showed that nut-cracking in squirrels consists of a number of acts—manipulating, gnawing, cracking—which develop in naive individuals without the benefit of practice; however, the integration of these individual acts into an adaptive sequence must be learned.

Further examples are found in the classical social "imprinting" phenomenon in which newly hatched nidifugous (not remaining in the nest, motorically precocious) birds such as ducklings and chicks show an innate drive for contact with a parent object during a genetically determined "sensitive period" in the early hours of life with the result that under normal conditions the characteristics of the parent object are learned. In all these examples of learning a *genetic program* that limits the range of items that may be involved or the time of learning, or both, is present.

The notion of the intercalation or interweaving of different behavior mechanisms in a sequence of actions is a primary mainstay of the ethological approach to the analysis of behavior. Lorenz's term for this, coined in 1937, is *Instinkt-Dressur-Verschrankung*, translated as *instinct-training-interlocking*. It implies that behavior is a continuous process of smooth integration of chunks of learned be-

haviors with innate ones. The learned components are considered to lend a flexibility to behavior and to promote greater adaptability in various environmental conditions. The innate components insure that certain reactions to specific stimuli will be made without the necessity of learning. These innate components, Lorenz stressed, can be seen most clearly in cases where, if learning were required, the possibility of survival would be greatly diminished.

Innate Behavior Mechanisms

We previously mentioned that the ethologists have postulated the existence of several innately determined (genetically programmed) behavior mechanisms. We shall now discuss a few of the most important of these mechanisms and show how these concepts are used to deal with motivation and reinforcement.

The *fixed action pattern*, or, more simply, fixed pattern, is one of the most fundamental concepts. In fact, modern ethology was founded on the independent discoveries of this phenomenon by Heinroth (1910) and Whitman (1898).

The fixed action pattern is defined as a genetically programmed sequence of coordinated motor actions. The animal can perform it without antecedent learning or previous exercise and without having seen another species member perform it. The fixed action pattern is *constant in form*, which means that the sequence of motor elements never varies. The form constancy is the same as that which occurs in the case of morphological features possessed by members of the same species.

These patterns are not equivalent to the well-known reflexes, nor are they chain reflexes. There is neurophysiological evidence (e.g., von Holst, 1935, 1937) which has been interpreted as supporting this contention. We cannot adequately discuss within the limits of this chapter the many and complex differences between the fixed action patterns and the reflexes which the ethologists have pointed out, but one of the most important of these differences is the fact that the frequency with which the fixed action pattern is performed depends in part on how long it has been since it was last performed; this is not the case with reflexes. This factor, involving the concept of *action specific energy*, will

be discussed later. Furthermore, the fixed action pattern can serve as a consummatory act that ends a sequence of appetitive behavior (also discussed later). No such appetitive behavior ending in the discharge of a reflex has been found.

Ethologists maintain that the notion of the genetic fixedness of fixed action patterns is supported by their appearance in animals isolated from other members of their own species. For example, Eibl-Eibesfeldt (1956b) has observed that squirrels reared in isolation and never given any objects to handle nevertheless attempted to bury nuts or nutlike objects in a bare floor upon their first encounter with them, making scratching movements as if to dig out earth, tamping the object in the floor with the nose, and, finally, making complete covering movements in the air. Thus fixed action patterns are presumed to be based on specific inherited central nervous system mechanisms. As we mentioned earlier, ethologists stress *inheritance*, or genetic coding, and not stereotypy, as the ultimate criterion of fixed action patterns if they are truly to be considered as taxonomic, species-specific characteristics.

As with other morphological and physiological characters, fixed action patterns have been found to be characteristics not only of species but also of genera and orders right up to the highest taxonomic categories. Fixed action patterns, as Whitman (1898) and Heinroth (1910) observed, have value in assaying the taxonomic relationships between species. Furthermore, evolutionary changes that occur in fixed action patterns are similar to those that may be seen in morphological or physiological characters. It is postulated that selection may favor the development of a fixed action pattern that has much survival value or cause it to die away or atrophy when it has no survival value. Ethologists have found behavioral rudiments (or vestigial behaviors) which remain even though they have little survival value. An example of this is the fact that mutant *Drosophila* with no wings still perform the wing-preening movements typical of the species (Heinz, 1949). It is possible to find a kind of ontogenetic development similar to Haeckel's (1866) well known "phylogenetic recapitulation" of organs: a primitive behavior pattern may be seen to precede a more recently acquired one.

during the ontogeny of the species. Thus, as Lorenz (1937) observed, there are some species of birds (the lark, the raven, and the starling) belonging to the *Passeres* whose original form of ground locomotion was hopping (as postulated on the basis of comparison with other species) but that now live on the ground and run. The juveniles of these species hop in biped fashion before they run.

Ethologists have recently extended their work from the study of the probable phylogenesis of fixed action patterns to their physiological bases, and have obtained evidence strongly indicating that these are indeed based on inherited and structured neurophysiological mechanisms. However, the fixed action pattern is still generally defined in purely functional terms.

The *innate releasing mechanism* is another very fundamental concept. It is fundamental because it recognizes the fact that an animal, like man, does not give a particular response to *all* of the stimuli it perceives, most stimuli are only *potential* ones. The animal may learn to respond to some of these. The fixed action patterns, in particular, are elicited by only a few of the stimuli in an animal's environment. These eliciting stimuli are called *sign stimuli*, or *releasers* of the behaviors they evoke. Corresponding to these releasers are the innate releasing mechanisms within the animal, which respond to these sign stimuli by permitting the discharge of internally produced energy for the performance of the relevant fixed action patterns. These innate releasing mechanisms are abbreviated as IRMs.

The simplicity of the stimuli that elicit innately fixed behavior in animals may be illustrated by innumerable examples. One is the case of the carnivorous water beetle *Dytiscus marginalis*. It does not react to the sight of prey, even though it has perfectly well developed compound eyes, but it does respond to the chemical stimuli emanating through the water from the prey. If it is presented a tadpole in a glass tube, the beetle will not attack, but if a meat extract solution is put into the water, the beetle engages in frantic searching behavior, clasping inanimate objects (Tinbergen, 1951).

Still another example of sign stimuli and innate releaser mechanisms is provided by

the work of von Uexküll (1909). The common tick apparently responds to only three environmental stimuli during the greater part of its adult life. First, photoreceptors in its skin guide the tick's movements to the brightest part of its environment, which usually results in the tick climbing up a bush or tree. Second, the tick responds to the scent of butyric acid, which is given off by warm-blooded animals, by releasing its hold on the twig upon which it has been resting and thus dropping downward. Third, when it encounters a temperature of approximately 37°C, usually on a skin area of a mammal, it attaches itself and begins to drink blood. The relationship between these three stimuli and these responses is innate in origin and certainly each of them ensures survival of the species.

The reactions of animals to sign stimuli is automatic. For example, a hen will fail to rescue a chick that it can see struggling under a glass bell, but that it cannot hear. On the other hand, it comes to the chick's rescue immediately if it does not see it but can hear its distress cries (Bruckner, 1933).

Although sign stimuli often consist of a simple quality such as butyric acid, they usually consist of relational characteristics between stimuli. For example, Koehler and Zagari (1937) found that the ringed plover reacts more strongly to an egg having black spots on a white background than to one having dark brown spots on a light brown background because the spots contrast more strongly with the background in the case of the preferred eggs. More remarkably, they prefer abnormally large eggs, even ones they cannot sit upon. Such stimuli that release a response stronger than that released by the natural stimuli are called *superoptimal*, or *supernormal* sign stimuli by ethologists. There are many instances of superoptimal sign stimuli.

Sign stimuli are considered particularly important in intraspecies and interspecies communication. Striking examples of this can be seen in the courtship behavior of many animals, particularly the showy displays of some bird species. The IRMs which respond to these sign stimuli are regarded as *organs* possessed by the animal, with special functions in the service of survival. The IRM is thought to operate as a receptor of key

stimuli and by necessity adapted to the world as it exists, so that it will respond only to stimuli that unfailingly characterize a particular biological situation, and no other. If a particular response is elicited by several sign stimuli belonging to a certain biological situation, then the presence of most of these stimuli in that situation guarantees the elicitation of the response in question. A pike cannot attach any releaser or sign stimulus to the fish on which it preys in order to differentiate it from a fisherman's lure, therefore the species must adapt the IRM accordingly. Otherwise, for lack of the ability to discriminate prey from a lure, the fish may be caught. Furthermore, it is obvious that the pike might not get enough to eat if it is unable to discriminate between prey and non-prey. Thus survival needs necessitate maximum discrimination capacities on the part of the IRM.

However, within a species or where inter-species communication takes place, natural selection can quickly result in the evolution of special sign stimuli or releasers that will be understood easily by the reacting animal. Ethologists have stressed that similar movements or behaviors performed by unrelated species for communication purposes have completely different meanings, for example, tail-wagging by the dog and by the cat. In related species the same movement is more likely to have the same social releaser value and meaning as well as the same genetic basis.

Further important concepts of ethologists can be seen in their treatment of the organization of behavior. Lorenz (1937, 1950) and Craig (1918) distinguished between two types of behavior: the *appetitive* and *aversive* behaviors, and the *consummatory act*. Appetitive behavior consists of initially variable searching behavior that becomes more and more specific until the simpler and more stereotyped consummatory act, in response to a releasing stimulus situation, is performed. Aversive behavior has some similarity with appetitive behavior, but it continues until a disturbing situation is removed and the animal reaches a state of equilibrium. Here the goal is not the discharge of any specific behavior patterns (consummatory acts) but the cutting off of aversive-appetitive behavior,

which normally consists of undirected locomotion.

Ethologists do not make an absolute distinction between appetitive behaviors and consummatory acts but postulate that there are many intermediate forms. These concepts, in effect, merely serve to mark extremes, with appetitive behavior being variable and plastic in character and the consummatory act being relatively fixed and stereotyped. The consummatory act, in fact, is the same as the fixed action pattern and is usually oriented toward specific directions by a *taxis*. Taxes, it may be briefly noted, are oriented locomotory movements steered to a certain direction by stimulation. An example is the movement of an animal toward a source of heat or light, the direction of the movement being determined by the intensity of the stimuli. In most cases the consummatory act is at the end of a long chain of behavior patterns involved in the appetitive behavior. In some cases, however, the consummatory act occurs so quickly that the appetitive stage is not readily apparent unless the opportunity to perform the consummatory act is withheld through the imposition of some obstacle. In this case appetitive behavior becomes plainly evident as the animal makes persistent attempts to perform the consummatory act in question.

Craig (1918) emphasized the notion that appetitive behavior is accompanied by a certain *readiness to act* and that many of the behavior patterns performed during the appetitive act are not innate but are learned. For example, a thirsty animal may go to a particular location for water because it has previously encountered water there. But the end action—the consummatory act—in itself is always innate, as is the actual drinking behavior. Further evidence of the innateness of the consummatory act is found in the occurrence of incipient consummatory acts or *intention movements* during the appetitive sequence, when the adequate stimulus for the consummatory action has not yet been received. In other words, we may observe incipient drinking movements in the thirsty animal searching for water.

Lorenz (1937, 1950) further enlarged upon this conceptualization of behavior by noting that there were observable fluctuations in the animal's readiness to perform fixed

action patterns. The ease with which a given sign stimulus elicits or releases the corresponding fixed pattern through the innate releasing mechanism (IRM) apparently is dependent upon how long it has been since the animal has last given that response and not on the animal's general fatigue. Lorenz thus developed the notion of *action-specific energy* to describe this phenomenon. According to his conceptualization, action-specific energy, that is, energy for a particular action, is produced continuously in an animal's central nervous system. At the same time, this energy is held in check by some inhibitory mechanism until the appropriate stimulus releases it to certain muscular systems and the reaction takes place. The longer the animal has gone without performing the action in question, the more easily this behavior can be triggered off or released. In fact, in the case of a very prolonged absence of relevant stimulation during an appetitive behavior sequence this behavior can go off without there being any observable stimulus present. This special case Lorenz called the *Leerlaufreaktion*, or *vacuum activity*. This phenomenon is very readily seen in captive animals deprived of their natural environment.

Lorenz (1966) cited as an instance of vacuum activity a hand-reared stalling that had always been well fed from a dish but that nevertheless would take off suddenly from its perch, fly to the ceiling to catch an invisible insect, return to the perch, and "eat" the insect. Likewise, dogs that are well fed will not lose their inclination to hunt and kill prey.

On the other hand, if the relevant stimulation is repeatedly given, the animal's response can decrease to the point where there is no response at all. A jumping spider (*Salticidae* family) catches prey by leaping at it rather than by building a web (Drees, 1952). A life-sized picture of a prey can be presented to this spider 30 to 40 successive times to elicit the attack response before it will cease responding in this way. If the spider is placed in a dark box for 2 hours, 10 to 20 more attack responses may then be elicited. Muscular fatigue is not the reason for the spider giving fewer attack responses than before, because if in the two-hour interval the spider is kept in a long runway with lights at each end alternately turning on and off, causing the

spider to run back and forth constantly, it will, at the end of this period, still make 10 to 20 attack responses to the picture of a prey.

It should be noted that Lorenz's notions of the building up and dissipation of the "reserve" of the readiness to react are an extension of Craig's notions of appetitive behavior seeking the discharge of the consummatory act, especially as seen in the presence of incipient consummatory acts before the actual releasing situation has been encountered.

Timbergen (1951) has further enlarged the Craig-Lorenz behavior scheme by proposing that there is a *hierarchical ordering of appetitive behaviors and consummatory acts* in animal behavior. Timbergen explained that a particular appetitive behavior does not usually end in a consummatory act but, rather, leads to a stimulus situation that initiates other, more specific appetitive behavior. A chain of appetitive behaviors gives rise to a temporal sequence of *moods* (*Stimmung*), that is, readiness to act, thought to be anchored in the central nervous system. Thus different levels of integration in behavior were seen by Timbergen to be organized into a hierarchical system.

An illustration of this is the reproductive behavior of the male stickleback, as described by Timbergen (1951). In spring the gradual increase in length of day brings the fish into a reproductive state. The males first begin migration into shallow fresh water with the females. The rise in water temperature as the fish go further inland, together with the visual stimulation arising from suitable territory consisting of heavily vegetated sites, is then the instigator of the entire reproductive behavior sequence in individual fish.

After a male has established his own territory his belly becomes red. This red belly, a nuptial coloration, is a characteristic of a male stickleback under a reproductive drive and serves a communication function, having an effect on both males and females of the species. At this point the male in the nuptial coloration begins to react to particular stimuli that previously had no effect on it. This can be shown by the fact that if males caught during migration are put together in a bathtub they will all remain together in a school with the exception of one, who establishes a territory by the diam plug chain

This chain is the only structured element in the bathtub, and it is for this reason that a territory is established there. Furthermore, it provides enough territory for only one male.

This male will now fight at the appearance of a stranger, begin to build a nest with any possible suitable material, and court passing females. Since the male's behavior depends principally on the stimulus situation, it is difficult to predict precisely what he will do. Fighting, for example, is released by the stimulus *red belly* on a male intruding into the fish's territory. But it is not possible to predict which of five known fighting movements will occur, since each is dependent on still further, highly specific stimuli. If the stranger bites, the territory owner will bite in turn, or if the stranger beats with its tail, the owner makes the same response. Fleeing will elicit chasing, and threatening will elicit threatening in turn. In summary, the stimuli emanating from an established territory will activate the fighting, building, and mating

drives. The more specific stimulus *red-bellied male* activates only a general readiness to fight, the specific movements made are dependent on even more specific stimuli.

Thus the ethologists conceptualize chains of behavior tendencies that are connected in higher and lower levels of integration. As Tinbergen postulated, the adaptive advantages of having a mood hierarchy rather than a stereotyped series of single, fixed action patterns lie in its flexibility in response to several situations. To Tinbergen and other ethologists it appears that there must be a structural organization within the central nervous system which parallels the lawfulness of behavior as indicated by the mood hierarchy. As a matter of fact, much neurophysiological work has lent strong support to such a notion. Weiss (1941) has shown a similar hierarchical organization of the central nervous system mechanism in motor processes. This hierarchical organization is almost exclusively below the level of the integration

Fig 1 Tinbergen's diagram of the hierarchical organization of instincts, superimposed on Weiss' diagram of the hierarchical organization of central nervous mechanisms. Weiss' highest level incorporates the same phenomena as those placed in Tinbergen's hierarchy (From Tinbergen, 1951)

of the goal-forming fixed action patterns. A diagram integrating the hierarchical theory of Tinbergen with Weiss's organization is shown in Fig. 1.

Tinbergen's hypotheses, of course, were intended as a simplifying scheme and do not cover all the possible complications that exist in the organization of behavior. For example, some of the behavior patterns present at the lower level, such as locomotion, can also be among the final effecting links in several different hierarchical organizations. Tinbergen's notions and findings are particularly valued by ethologists because they link physiology of the central nervous system to behavior, an area of research which even at its very beginning represented a task of immense magnitude.

The neurophysiology of behavior is currently an area being worked on with great fervor. Such ethophysiological studies as those of W. R. Hess (1943, 1944, also Hess and Brugger, 1943 a, b, Brugger, 1943), and especially those of von Holst and von St. Paul (1958, 1960, 1962), have not merely served to provide considerable evidence for Tinbergen's schema of behavioral organization but have also demonstrated the validity of such ethological concepts as action-specific energy or displacement activities, which were originally purely hypothetical constructs. Also of very great importance in von Holst's work are the investigations involving the electrical elicitation of different drives at the same time.

There are many instances, according to ethologists, in which the observed behavior is the result of more than one drive acting upon the individual at the same time. This, of course, makes the analysis of behavior quite complex. Several types of such behaviors have been postulated: *successive ambivalent behavior*, *simultaneous ambivalent behavior*, *redirected behavior*, and *displacement behavior*. These are not considered mutually exclusive behaviors and can occur together in the same sequence of actions.

In the case of successive ambivalent behavior it is observed that the animal alternates between incompletely performed movements associated with conflicting drives. A classic example of successive ambivalent behavior is that of the male stickleback's "zig-zag" dance in the courtship of the female

(Tinbergen, 1951). Tinbergen described the dance as an expression of two conflicting tendencies: to attack the female and to lead her to the nest. The "zig" toward her is actually incipient attack, the "zag" leading her toward the nest reflects sexual motivation. Van Iersel (Lorenz, 1966) confirmed this and showed by experimentation that the lengths of the zigs and zags indicate the relative strengths of the aggressive and sexual motives. Furthermore, the alternation of the motivations has actually become ritualized in the stickleback, according to Lorenz (1966), so that a rhythmical zig-zagging occurs in the courtship sequence.

Simultaneous ambivalent behavior is apparent when both of the conflicting drives are performed at the same time. For example, the "Halloween" threat posture of the cat, according to Leyhausen (1956), results from the animal retreating more rapidly with the front paws than with the rear ones, or by his advancing with the rear paws while retreating with the front ones.

Redirected behavior and displacement behaviors, two other types resulting from the simultaneous presence of more than one drive, are two concepts which have been utilized frequently by psychiatrists and students of human behavior. We shall discuss their use of these concepts later.

Redirected behavior is postulated when one behavior is inhibited or suppressed by another motivation with the result that this behavior is directed to an object different from the one that really elicits it. For example, a male black-headed gull feeling aggressive toward its mate is at the same time inhibited from actual attack. Hence the male gull may redirect the aggression by attacking other birds or even an object if no third party is available.

This is a relatively common phenomenon, in fact, many elements of courtship display have been interpreted as redirected aggression. Several animal species normally do not have close contact between members, and courtship activity serves as a means of handling the aggressive responses that the close contact entailed by sexual reproduction elicits. As Baerends (1958) has shown, redirection of aggression in the male cichlid fish *Cichlasoma meeki* during courtship appears in incipient attacks toward plants

Courtship behavior, of course, performs other functions, such as the synchronization of the physiological cycles of the male and female.

Moreover, aggression is one of the factors promoting sex recognition in a wide segment of the animal kingdom, especially where there is no distinctive sexual dimorphism. Oehlert (1958) demonstrated that in both of the two cichlid species he studied, *Cichlasoma biocellatum* and *Geophagus brasiliensis*, when two strange fish meet, three drives—sex, aggression, and fear—are always aroused simultaneously. However, the mixture of these three drives is very different for the male and female sexes in both species. In the males the sexual drive mixes with aggressive behavior very easily but becomes suppressed by even the most minimal flight drive. In the female, on the other hand, the sexual drive superimposes with the flight drive with no difficulty, but aggression immediately inhibits sexuality. In this way the formation of male-female pairs is guaranteed and the avoidance of homosexual pairs is accomplished. In several other species it has been observed that fear dampens male sex drive, while aggression does the same for female sex drive.

Hinde (1959) has suggested that in closely related sympatric species the sole differences in courtship behavior may be in the strengths and relative intensities of the three drives of aggression, flight, and sex. It is these differences that can have the effect of preventing the occurrence of hybridization between these closely related species.

The final type of mixed drive behavior to be discussed is displacement activity. This is seen in conflict situations in which the animal shows behavior patterns that do not belong to either of two conflicting drives. At first such "irrelevant behavior" appears anomalous, but it has been observed that a particular irrelevant act is often typical of a particular set of conditions. For example, fighting cocks may suddenly peck at the ground as if they were feeding (Lorenz, 1935; Tinbergen, 1939) and similar instances have been seen in other birds. The "irrelevant feeding" in this case, according to ethologists, results from a conflict between aggressiveness and fear. It appears to some ethologists that the neurological activity generated by the two conflicting behavior patterns "sparks over"

into the third inappropriate behavior when these behaviors are blocked. Thus when an animal faces an opponent which it is motivated to attack but which it is afraid of, it may decide instead to peck at nonexistent food, according to Tinbergen (1952).

Many types of displacement activities have been observed and described by ethologists. Such activities often occur when fighting and escape drives appear to be simultaneously aroused. They are also very common in sexual situations. They can, of course, be aroused by combinations of other drives as well. Finally, they are apparently more likely to take place when the conflicting drives are relatively intense.

The validity of the displacement activity construct has been considerably supported by the neurological work of von Holst and von St. Paul (1960, 1962), who studied the effects of arousing different drives simultaneously in an animal by means of electrode implants in the brains of chickens. At any time that two specific motivations were stimulated simultaneously, these researchers always observed the same specific ambivalent, redirected, or displacement response by the animal. This indicates the same type of lawfulness found in nature wherein specific ambivalent, redirected, or displacement actions are typically elicited by highly particular sets of conditions for each.

THE DEVELOPMENT OF BEHAVIOR

The Problem of the Phylogenetic Scale

For many years comparative psychologists and other investigators of animal behavior in this country utilized the laboratory rat almost exclusively in their experimental studies. The many experiments on learning using rats as subjects were carried out with the assumption that the results of such studies were directly applicable to learning processes in all other animals, including human beings, since it was believed that learning processes are qualitatively similar for all species. With such a premise it appeared patently obvious that it would be unnecessary to study these processes in several different species. The rat was considered representative of all animals.

Today, no one is this naive, nevertheless, there is considerable need for sounding cautionary notes in interpreting the behavior of

one species on the basis of experimental results obtained with another species. By virtue of their emphasis upon the genetic transmission of behavior characteristics, ethologists have shown from the first a strong awareness that it is necessary to distinguish carefully not only among species but also breeds within species and even strains within breeds. It has been only recently that behavior geneticists in this country have begun to appreciate the fact long stressed by ethologists that experimental results must either be considered as restricted to the animals from which they were obtained, or else tested on many species before they are used as the basis for any generalization.

Yet there is sometimes an unwarranted tendency among seemingly hard-headed scientists to think in terms of explaining human behavior on the basis of animal behavior. This does not in any way imply that the notion of behavioral continuity between species should be denied. What is meant is that just because something is known about the effects of early social experiences on the later adult behavior of geese, for example, we cannot make inferences about the nature of the effects of early life experiences on the adult behavior of human beings. Even if experiments on the effects of early social experience are carried out using primate species, we cannot necessarily make generalizations applicable to human beings. Just as inferences cannot be made regarding human visual perception on the basis of experiments carried out on lemurs, which lack color vision, we cannot make extrapolations regarding the social or intellectual behavior of man from data obtained on monkeys or apes.

An extreme case of unjustified anthropomorphism is given by the writings of Monboddo (1774). Monboddo, in attempting to prove that speech and language were not original attributes of man's behavioral capacities, argued that the orangutan and man belong to the same animal species on the basis of anatomy and behavior. The name "orangutan," in fact, comes from the aboriginal native word meaning "wild man," and there were attempts to call this animal *Homo sylvestris*, thus placing it in the same genus as man. So evidently anthropomorphism is nothing new!

Not even extrapolation from one lower primate species to another is justifiable. For ex-

ample, there is a very wide variety of social systems among different primate species. South American howling monkeys have clans with no dominant male, spider monkeys have a similar structure, but contrary to most ape or monkey groups the female is emancipated and takes an important role in social activities. Rhesus monkeys have, generally speaking, a harem-type social structure, with a dominant male heading a group. The baboon, on the other hand, may have aggregations of harems. With the gorilla we find a social structure in which there may be a single male and some females and young. The only primate that seems to fit at least some of our own notions of "proper" human social structure is the Lai gibbon, an animal that is supposedly monogamous with two parents raising the young and keeping their infants with them.

Although infant-infant social experience can overcome the deleterious effects of three months of total social deprivation in the case of the rhesus monkey (Harlow and Harlow, 1962), we cannot necessarily draw the conclusion that the same would be true for another primate species such as the Lai gibbon in which there is apparently little infant-infant interaction under normal conditions. Furthermore, there is certainly no justification for making any suggestion that a similar phenomenon may be found in man, particularly since rhesus monkeys apparently can overcome the effects of total social deprivation for the first three months of life, whereas all the evidence to date appears to indicate the rather drastic effects of only *partial* social deprivation during the first six months of life in human beings (e.g., Bowlby, 1951).

Thus it is apparent that there is a need, through an exhaustive and comparative study of several species, to determine the relationship between social structure and normal behavior. Then and only then is it possible to set up experiments in the laboratory that can take advantage of this information, and permit us to make some accurate predictions about specific effects of early social experience on later social behavior in other primates and human beings.

It certainly has been implied often enough that along all intellectual lines the monkey is the animal closest to man. But there is one capacity in which an animal other than a monkey (or ape) comes closer to man: the ability

to pick out the correct stimulus in terms of the number of discrete components it contains Koehler (1943) showed individual birds a small box having a lid with a number of irregular black blotches randomly distributed on it. Then the birds were shown a group of several boxes, each having a different number of blotches on their lids. Although these boxes were all present simultaneously, the birds were able to select the one that had the same number of blotches on it as did the sample, even though the sizes and arrangement of the blotches were different. This box contained a food reward. These birds could do this with any number of blotches up to six or seven, the same level as that achieved by people. Kuhn (1953) and Hicks (1956) have shown that such a task is more difficult for the rhesus monkey to do since stimulus characteristics such as density, size, color, and shape interfere with their ability to use purely numerical cues; their maximum discriminable number was three or four spots. It may be mentioned that Kellogg (1961) suggests that it is entirely possible that the intelligence of the dolphin is more like man's than is the intelligence of any lower primate, since the dolphin has an absolute brain weight and a brain weight-body weight ratio that are closer to the corresponding values in man than those of any other animal.

All these considerations regarding the phylogenetic relationships of behavior are entirely consistent with the ethological standpoint. Both continuity of behavior as seen in closely related species and taxonomic groups as well as behavioral differentiation between species occupy prominent positions in ethological thinking.

Ritualized Behavior and Evolution

Fixed action patterns, as we stated earlier, are subject to evolutionary forces, with the evolutionary changes mentioned being the same as those that are known to occur with morphological or physiological features.

The ethologists have postulated that there are two stages in the evolution of motor patterns. In the first stage there is a quantitative increase or decrease in the basic motor elements, perhaps actual disappearance in some cases. In the second stage the basic motor units, almost unalterable in themselves, are coupled to or disengaged from each other.

This coupling of previously independent basic motor elements into a new fixed sequence is part of the phylogenetic process that Huxley, an English naturalist, called *ritualization* in 1914.

Another part of the postulated ritualization process is the phenomenon in which a recently formed fixed action pattern may become motivationally autonomous of the situation that originally aroused it, or dependent upon another motivation. An example of this phenomenon has been described by Lorenz (1941) on the basis of the different forms of the female's "inciting" movement during courtship in the different species of swimming ducks (*Anatinae* family). In the original form of this behavior (as it still exists in some species) the female attempts to separate the male from the group by inciting fights between her partner and other males. To do this she runs toward the strange male, but at a certain point fear overtakes her, and she runs back toward her mate. When she is close enough to him, however, aggressiveness again takes hold of her, and she stops and turns toward the strange male. This, Lorenz interpreted, results in her standing at the point of equilibrium, near her mate, but stretching her neck toward the other male, making inciting movements. Here the angle between her body and her stretched-out neck is a function of her position and those of the two males. This behavior constitutes the unritualized form of incitement.

In some other species the behavior has become fixed to the point that the female simply stands near her mate and moves her head back over the shoulder, regardless of where the strange male is. In this case it appears that the movement is performed solely as a courtship act by the female. Lorenz considers the interpretation of this behavior as ritualized incitement to be further justified by the fact that still other species perform actions which are intermediate between these two extremes when in a similar situation (Lorenz, 1941).

In a third, less common phenomenon postulated in the ritualization process, the fixed action pattern ceases to be performed in different degrees of intensity and is executed in one intensity only. In such cases the degree of motivation is not expressed in the intensity of the behavior but in how often the behavior

is repeated, much as the urgency of a telephone call may be recognized by the persistence of ringing rather than in loudness. All fixed patterns with a single or typical intensity function as means of communication between species members. Selection pressure would in these cases operate to enforce a quite simple and unmistakable form of the movement, according to Morris (1957).

The comparison of different species is the principal means by which the evolution of certain behavior patterns is deduced by ethologists. During the course of ritualization original behavior patterns are very often changed into mimetically exaggerated performances through the increase of their amplitudes and frequencies. In addition, these behavior patterns are thought in some instances to be transformed by the evolution of additional structures. For example, the ceremonial feeding seen in the courtship behavior of many *Gallicinae* birds and pheasants often appears to have been transformed and accentuated by additional shaking movements, feather spreading, swelling of exposed vascularized skin structures, and sounds in one or another of these species.

Since behavior patterns are regarded as species characteristics, they can be considered homologous in related species, as the preceding example of the female duck's "inciting" movement during courtship indicates. As a matter of fact, ethologists use the very same kind of criteria for determining behavior homologies that comparative morphologists use for bodily features (Remane, 1956). The three criteria they rely most heavily upon are (1) *similarity in structure*, that is, similarity in the spatiotemporal pattern of muscle contractions or movement, (2) *similarity in order of occurrence of movements*, and (3) *linkage by intermediate stages in different species*.

Thus the more fixed action patterns of different species correspond with each other in their special characteristics—such as internal causal factors and releasing situations—as well as in the coordinations themselves and the more complex these characters are, the more likely they are to be classified as homologies. Sometimes, of course, ethologists caution similar structures, bodily or behavioral, can evolve independently of phylogenetic relationship in different groups of animals as a result of adaptation to the same environmental conditions,

and in such cases they would be *analogues*. For example, food hiding in very different species may at first look homologous, but the similarity would actually be due to function and not to common history, since there are only a few ways in which food can be stored.

Two somewhat different movements, however, may be considered homologous to each other if they occur in the same place in a specific sequence of movements performed by the two related species in question. The courtship of the female by the males of the species *Tilapia mossambica* and *Tilapia nilotica* consists of the same sequence of movements, *a, b, c, d, e, f, g*, but at one point in the sequence the tail-wagging movements are comparable but different in the two species (Baeleends, 1958). Furthermore, two different movements performed by different species may be considered homologies if intermediate stages of these movements are found to be performed by other related species of the taxonomic group. It is considered necessary in such cases to have enough instances of intermediate stages between disparate forms for comparison as a cautionary measure to prevent the mistaken homologizing of similar-appearing but different activities in two related species. An illustration of this kind of homology has been provided by Lorenz (1941). Males of many duck species perform an up-down movement with the head and bill while courting the female. Some species, however, do not perform this action, in its place they make a drinking response. Not only do these two different movements have some similarity, but other duck species show a range of forms intermediate to these two behaviors, leading all the more forcefully to the conclusion that these two different behaviors constitute homologies of the different species in question.

An interesting example of homologous behavior is a specific movement that is now thought to be phylogenetically very old and extremely widespread among four-limbed vertebrates. This is the scratching movement. Thorndike (1899) observed that "the frog, lizard, chick, and cat all react to irritation of the head by scratching with the hind leg with a quick, repetitive motion that is startlingly alike in the last three. Here we have an instinct which apparently ranges over a subkingdom." This scratching movement, made

by the hind limb raised over the front limb in the majority of these species, was subsequently discussed in some detail by Heimoth (1930) and more recently by Lorenz (1958). Many birds have been observed to lower their wings in a rather peculiar way and reach forward in front of the shoulder with the leg, in spite of the fact that it would seem to be less clumsy for the bird to move its claw directly to its head without moving its wing, which is normally folded on its back and out of the way. Apparently the bird reconstructs the spatial relationship of the body that was possessed by its four-legged reptilian ancestor and thus behaves as if it had an obstructing front leg. A few bird species such as stork, heron, and pigeon have developed the habit of scratching the easier way, but most have retained the original technique. There is even one species, according to Lorenz (1958), which has learned to eat with its claws and brings them directly to the head. But when scratching, it still brings its claw over its lowered wing and cannot be trained to do otherwise.

Other very clear examples of homologous behavior patterns are found in the courtship behaviors of ducks, as studied by Heimoth (1910) and Lorenz (1941) and in the same behaviors of pheasants and related fowl (Schenckel, 1956, 1958).

Ethologists also believe that the concept of *homonomies* applies just as well to behavior patterns as to morphological forms. Morphological homonomies refer to a series of organs possessed by the same species which have undergone differential modification. For example, the feeding legs of crustaceans have been found to be in actuality modified walking legs, because there are a series of other limbs between the feeding legs and the walking legs which represent intermediate forms between these two types. Behavioral homonomies are postulated when animals perform both ritualized movements and the original ones from which they have been derived. An illustration of behavioral homonomies is given by grooming movements, which are used in social interactions as an expression of friendliness and peaceful intentions. A friendly dog, as is well known, greets by licking and nibbling. In some other animals movements exactly like those used in grooming are also used as a greeting ceremony to a member of

the same species before any actual physical contact has been made.

While in many cases there appear to be extremely close similarities between highly ritualized movements, movements that appear obviously ascribable to homology, ethologists exercise caution in applying the concept. This is because expressive movements often serve the function of conventional signals in a given species. Thus it is postulated that what a given movement signals is a phylogenetically evolved convention, just as the meanings of individual words in human languages are conventions. Hence different meanings may be expressed by similar movements in different species—such as tail-wagging in the dog and cat—depending on the motivational situation from which they have derived. Also, in cases where similar movements appear in entirely unrelated species and there is no spread of these movements among other species in the same taxonomic groupings to provide evidence of phylogenetic progression, such movements are considered to have been acquired independently and are certainly analogous. The rattling of the tail by the rattlesnake and the porcupine is such a case, for two different taxonomic classes, reptilian and mammalian, are involved, and we do not find numerous instances of tail-rattling among other species of the vertebrate subphyla to which they both belong.

At the present time ethological research on the genetics of behavior is still in its infancy, but it has every promise of becoming increasingly important and many theoretical implications concerning the mode of genetic transmission and the origin of behavior have already been made. Ramsay (1961), for example, reported on studies of the transmission of courtship behavior patterns in crossbred progeny of different species of ducks which he had observed since 1956. He crossed a male black duck and a female mallard. The courtship displays of the two parent species are essentially identical, but the F_1 generation hybrid performed several sequences that were characteristic of neither parent species. In one case there was an elimination of one movement in a sequence, it never gave the nod-swimming following the head-up tail-up display. This display is omitted in the mallard only 7% of the time and in the black duck 20% of the time in the typical sequence.

These percentages were based on approximately 75 recorded observations for each animal. In the hybrid the movement sequence of bill-shaking, grunt-whistle is reversed. Sometimes in the parent species this sequence is tail-shaking, bill-shaking, grunt-whistle. In the hybrid this is reversed to grunt-whistle, tail-shaking, bill-shaking. This hybrid also showed other occasional deviations from pattern such as head-up-tail-up, down-up.

Von de Wall (unpublished study) has also made studies of the genetic basis of courtship behavior in hybrid ducks. His hybrids performed motor elements in courtship that, even if not present in either of the different parent species, were distributed in the *Anatinae* family (swimming ducks) to which these species belong. Some hybrids performed integrations and coordinations that, again, were not present in any of the parent species but were present in certain other species of the *Anatinae* group.

These studies have supported the ethological postulation, originally based on comparative studies, that certain complete series of fixed action patterns were primary, or original, in a taxonomic group, but that the absence of some of these fixed patterns in any member species of that taxonomic group is a more recent phenomenon. Although the basic components, or fixed action patterns, do not change their character as a result of crossing, their sequence can be rearranged.

Courtship behavior is not the only behavior to which ethologists have applied their concepts of genetic transmission of behavior. Dilger (1962) has investigated nest material carrying behavior in F_1 hybrids of a male *Agapornis roseicollis* and a female *Agapornis personata fischeri*. Both of these species cut strips of paper or leaves and take them to the nest to be used for building. *Fischeri* carries the strips to its nest in its bill. *Roseicollis*, however, tucks the strips under the lower back and rump feathers, with their plumage erect while the material is being tucked, and then flies off to the nest. The remarkable thing about this difference in behavior between these two closely related species is that both have body feathers modified with tiny hooks whose function is to bind the feathers more closely to the body, but *roseicollis* also uses them for holding strips of material under the feathers.

The sequence of the *roseicollis* female's behavior is composed of the following elements: the cutting of the strip, grasping of the strip, bringing the head back over the shoulder, erecting the lower back and rump feathers, tucking the strips between these feathers, bringing the head into the normal position, and lowering the back and rump feathers. This sequence is an innate pattern, the only changes due to experience being the subsequent standardization of the size and shape of the strips. Strips that are accidentally dropped are not picked up, but new ones are cut to take their place. *Fischeri*, which carries the cut strips in its bill, however, will pick up strips that lie on the ground.

The nest-building behavior of the F_1 hybrids resulting from a cross between these species is most interesting. They cut the leaves and tried to tuck them under their feathers, but their attempts never succeeded, for a variety of reasons. Sometimes the birds would tuck the strip under the feathers but be unable to let go of it. In such cases, after repeated attempts had been made, the strip would be abandoned and a new one cut. In some other cases the hybrid might be able to let go of the strip, but the feathers would fail to hold the material, probably from not being pressed against it. Sometimes the hybrids would try to put the strips in inappropriate locations such as the breast, belly, flanks, or wings. Quite commonly, the tucking behavior would change into preening behavior. It was very clear that the hybrids were displaying a conflict between the tendency to carry the material in the feathers and the tendency to carry it in the bill. They were successful in getting material to their nests only when they carried it in the bill. But even when they carried the strip in the bill, which happened very rarely during their first attempts at nest building, they engaged in tucking movements.

After two months of experience the hybrids made fewer tucking attempts before carrying leaf strips in the bill to the nest. Nevertheless, two years passed before their behavior became more efficient and more like their *fischeri* parent's. Even so, they continued to perform tucking movements. These movements themselves were performed better but were never successful as a means of carrying leaf strips to the nest.

Among other behaviors that have been studied with respect to genetic transmission are exploratory tendencies, temperature preferences, and even cocoon-spinning. Ethologists maintain that it is already evident that behavior patterns or their components are genetically transmitted from generation to generation in a fashion similar to that for physiological or morphological characteristics.

Intraspecific Aggression

Although we have touched upon the role of aggression in mixed drive behavior and especially in courtship behavior, we shall briefly consider specifically the function of aggression between members of the same species because of the recent attention given by Lorenz (1966) and others to aggression in human behavior.

As with other behaviors, ethologists have studied aggression as it occurs in different animal species in terms of its function and survival value for the species concerned. Under natural conditions aggression has been always found to have a positive function: the optimal spacing of the individuals of the species about the available habitat of that species. In fact, all species require territorial spacing unless the special interests of a social organization demand close aggregation of its members. Otherwise the ecological niche of the area that serves a particular species will not have sufficient supplies to support all resident members of this species. The same area, of course, can support different species utilizing different niches. Lorenz (1966) has remarked that this is analogous to the fact that it is generally disadvantageous to society and to mechanics for all mechanics to live and ply their trade in the same area, but a grocer and a mechanic do not take trade away from each other.

Other positive functions of aggression have been known since Darwin (1859) asserted that it was always favorable to the future of a species if the stronger of two rivals takes possession of either the territory or the desired female. These, however, are special cases, subordinate to the principal value found in the proper spacing of the species. Defense of the young is another positive feature of aggression. Lorenz (1966) has suggested that in such animals as bison and

baboons family defense has evolved the rival fight which in turn has selected for males more powerful and stronger than the females.

A particularly interesting feature of aggression has been pointed out by Lorenz. This is the fact that strong and faithful individual bonds (e.g., enduring pair formation in mating) are found only in species in which there is measurable aggression. Whereas aggression can be found without personal bond formation, or "love," Lorenz asserted that there is no love without aggression. The differentiation between family, friends, and strangers as individuals appears most strongly manifested in aggressive behavior; this occurs in both humans and other animals.

Innate Behavior in Man

For several decades behavioristic psychologists in the United States have strongly resisted the very notion of innate behavior in man. There seems to be some tolerance toward the notion of innate behavior in animals, perhaps because for so many centuries the notion of instinctive behavior was applied only to animals on the basis of theologically derived concepts of the distinctiveness of man and his superiority over all lower animals. Man, according to these concepts, could guide his actions by reason, whereas animals had only instincts to lead them to act.

However, ethologists believe that it is possible to apply many of the same concepts they have developed with respect to the study of animal behavior to human beings. Darwin (1872), of course, had an ethological approach to human behavior. Craig (1918), one of the first modern ethologists, in discussing appetitive and consummatory behaviors, remarked, "all human behavior runs in cycles which are of the same fundamental character as cycles of avian behavior."

Certainly human behavior is extremely complex and plastic. The degree of learning in the determination of behavior is probably higher in man than in most other animals. But in many instances ethologists have drawn parallels between human and animal behavior, particularly from a phylogenetic viewpoint. Such parallels, of course, are made with the understanding that in no case do they necessarily imply anything more than

an illustration of how ethological concepts may be applied as tools for the analysis of human behavior. At present studies of animal behavior can provide only *ideas* regarding human behavior. Ultimately, we must, if we are interested in the behavior of the human animal, do research with the human being as a subject. This, of course, is not a simple matter, since if the human is both experimenter and subject, numerous biases inimical to objectivity are present. We must guard against such biases as well as against anthropomorphism.

Lorenz (1943) has postulated that there is a releaser which is very widespread in the animal kingdom. This releaser is the quality we call "babyishness." If the young and adults of several species are compared for differences in bodily and facial features, it will be seen readily that the nature of the differences is apparently the same almost throughout the phylogenetic scale. Lambs are shorter and much heavier in proportion to the torso in babies than in adults. Also, the head is proportionately much larger in relation to the body than is the case with adults. On the face itself, the forehead is

Fig 2 Comparison of visual features provided by morphological characteristics of infantile and adult forms of four different species: human, rabbit, dog, and bird. While the infantile characteristics release parental responses, the adult ones do not. (From Lorenz, 1943)

more prominent and bulbous, the eyes large and perhaps located as far down as below the middle of the face, because of the large forehead. In addition, the cheeks may be round and protruding. In many species there is also a greater degree of overall fatness in contrast to normal adult bodies. Figure 2 shows a group of heads of young and adult humans, dogs, rabbits, and birds. Lorenz (1943) also remarked that the doll industry has conspicuously utilized these physical characteristics and, in fact, make dolls and other toys function as superoptimal releasers of man's mothering response.

In the light of Lorenz's suggestions, Cann (1953) conducted a study that gauged the positive responsiveness of men and women, single and married, parents or childless, to pictures of infant young and adults of several different animal species. These pictures were shown as a series of 53 pairs, each pair consisting of one baby and one adult of the same species, both printed in the same size. It was found that significantly more of the "baby" pictures were preferred over the adult pictures by single women and by childless married women than by single men and childless married men. While women at different ages and marital and parental states tended to show about the same high degree of responsiveness to the pictures of the babies, the responses shown by men tended to increase as a function of marriage and parenthood. The men whose wives were expecting for the first time showed greater responsiveness than did single men, those who had children showed even greater responsiveness. However, the men never exceeded the women in responsiveness.

The status of "babyishness" as a releaser in human beings has been further studied by Hess and Polt (1960) and by Hess (1967). In the earlier study it was found that when people look at pictures which arouse their interest their eye pupils enlarge significantly. There was also a difference between men and women in their pupil responses to pictures of babies. All these results were independent of illumination conditions. Women's pupils enlarged considerably when they looked at such pictures, whereas men's pupils showed very little change in size. This result, of course, substantiates Cann's earlier results.

Subsequently Hess (1967) reported on the

results of showing people progressively stylized drawings of human or animal faces. This stylization was in a trend toward greater and greater babyishness in the appearance of the faces, culminating in the Walt Disney-type portrayal of infant and animal babies. Correspondingly greater pupil responses are elicited by greater babyishness, a result which appears to support the ethological notion that the quality of babyishness definitely has positive appeal to people. This shows also that in man, as in other animals, social prescriptions and customs are not the sole or even primary factors that guarantee the rearing and protection of babies. This seems to indicate that the biologically rooted release of "babyishness" may have promoted infant care in primitive man before societies were ever formed, just as it appears to do in many animal species. Thus this release may have a high survival value for the species of man.

Not only the quality of babyishness but also the apparently unconscious perception of the pupil size of other people during interpersonal contact appears to influence pupil size and other behaviors of people. Studies by Hess (1965), Stass and Willis (1967), and Simms (1967) have confirmed that pupil dilation itself functions as a signal in interpersonal communication, especially in heterosexual confrontations. In other words, the perception, even if not on the conscious level, of increased pupil size in a person of a different sex acts as a release and triggers off a pupil size increase. This phenomenon is analogous to the "social releases" which ethologists have observed in the social behavior of animal species. In ethological studies it has been found in very many instances that movements or specific behaviors of one animal act as "releases" eliciting certain responses in the other animal perceiving these behaviors. Such responses can elicit still further behaviors in the original partner of the interacting pair.

Not only the concept of releases but also that of fixed action patterns is applicable to human behavior. In this connection it is interesting to note that Piaget, the Swiss child psychologist, has postulated that the child and infant have organized dispositions to perform certain invariant action sequences, or "schemas," as he has termed them (see Piaget's chapter 5 in this book). Piaget's con-

cept of schemas, as discussed by Flavell (1963) has certain similarities to the fixed action patterns, however, there are very fundamental differences in that Piaget includes learned action sequences and specifies that they need not be overt. Thus innateness is not a criterion for the schema, although the true fixed action pattern would in all probability be regarded as a schema by Piaget, since reflex acts are considered schemas. Piaget further postulates that experience in the use of schemas results in their differentiation, hence it does not appear that he directly considers endogenous maturation as a factor in the ontogeny of schemas.

Nevertheless, the principal similarity between Piaget's schemas and the fixed action patterns is a striking one: a single schema constitutes a class of *similar action sequences*, these sequences of necessity being strong, bounded totalities in which the constituent behavioral elements are tightly interrelated. Piaget himself wrote "every schema of assimilation constitutes a true totality, that is to say, an ensemble of sensorimotor elements mutually dependent or unable to function without each other" (Flavell, 1963, p. 54). Of further and considerable interest is the fact that Piaget considers the child to evidence functionally invariant, *organized* behavior totalities from birth onward, with these totalities set in motion again and again. Although the child's use of schemas does have a collective function in the apprehension of reality, the child's behavior toward the environment definitely is not considered random or fortuitous. The child has strategies, or tools, that is, *psychological organs*, in the form of schemas, to deal with aspects of the environment which are responded to selectively and specifically. It is particularly evident early in development that the elementary schemas such as grasping tend to run off whenever an appropriate stimulus is presented to the child. The belief in the lack of randomness in behavior elicitation is similar to the ethological viewpoint on animal behavior. While the schemas are defined as *cognitive* functions, Piaget considers that they have underlying action systems in the brain and, according to Flavell, has made some speculations on these.

The smiling behavior of small babies is both a fixed action pattern in the ethological

sense and a schema in Piaget's sense. Smiling therefore can be analyzed by ethological methods and in fact exhibits many of the phenomena which we have described for innate behaviors of animals. Eibl-Eibesfeldt (1967) is one ethologist currently studying smiling behavior in human beings, both children and adults.

We have discussed the quality of babyishness as an elicitor of responses in people, it also seems that people elicit responses in babies, mostly those of smiling. Such smiling responses normally serve to further increase the appeal of babies to people and therefore serve a definite survival function in that both the babies and their caretakers are bound to each other. (See Maccoby, Chapter 23, and Kessen, Chapter 10, both in this book, regarding the social value of smiling behavior.)

The earliest studies of the smiling response of babies dealt with the qualities of the stimuli which elicit smiling and the ontogeny of the response itself. It now appears, according to ethological thinking, that the human face constitutes an innate releaser of the smiling response. The investigations of Spitz and Wolf (1946), Wolff (1963) and Wilson (1963) have shown that the face has an innate positive value in eliciting smiling in babies. Wilson (1963), in particular, showed that association with food during nursing is not the factor that promotes the effectiveness of the face as an evocator of smiling. Food itself therefore is not the major factor in the socialization of human babies as reflected by the smiling response. This is analogous to the observation that during the primary socialization of newly hatched precocial birds, the young will follow the parent long before it has any need for food, as a result of this initial social experience the young bird becomes socialized to its own species. This is the phenomenon of imprinting, one of the areas in which ethologists and psychologists have done a great deal of investigation. Later we shall briefly discuss the relevance of the social imprinting phenomenon for the study of human development.

It is of great interest that as long ago as 1872 the phenomenon of smiling as a universal characteristic of the human species was observed by Charles Darwin, one of the early forerunners of present-day ethology. Darwin noted that smiling could be seen in

babies of every literate and preliterate culture with which he had come into contact. The ubiquity of this behavior has been expressed well by Wolff (1963), who termed smiling a "congenitally present expressive movement."

One of the strongest supporters of ethological concepts in application to human development, especially in the sphere of social behavior, has been John Bowlby (1957, 1958), who views smiling in the human infant as an instinctive behavior pattern and has drawn certain analogies between imprinting and the human mother-child relationship (discussed later). In outlining the similarity between smiling in the infant and innate behavior patterns found at the animal level, Bowlby (1957) presented the hypothesis that smiling behavior increases the infant's chances of survival since it makes the infant more appealing to the mother. Bowlby further suggested the possibility that during evolution there has been a selection factor favoring smiling behavior in man and that infants without this behavior pattern had a much higher mortality rate. Bowlby also noted that there is a specific stimulus which will elicit smiling in the infant. This stimulus consists of the schema of the human face and this can, of course, be considered a releaser in the ethological sense.

Wolff (1963) reported a great many concepts regarding the smiling response of babies which are completely consistent with concepts that have been proposed by ethologists with respect to fixed action patterns, even though Wolff himself is not an ethologist and he declines any commitment as to whether he regards smiling as an innate behavior. Nevertheless, Wolff has strongly posited that "the infant is congenitally equipped to smile." He also observed smiling by premature babies, and on the basis of this concluded that the morphological mechanism for smiling is present extremely early in development. "the smile is not a contraction due to gas pains," Wolff affirmed.

Wolff, like Friedman (1966), noted that smiling occurs in newborn babies and those less than a month old in the absence of any external stimulation. This observation indicates that smiling at that time is aroused by central factors, not solely by peripheral stimulation, a notion which ethologists have

vigorously championed with respect to innate fixed action patterns. Although this fact and the fact that blind babies also smile (Freedman, 1966, Eibl-Eibesfeldt, 1967) mean that smiling is not released solely by an external facelike visual stimulus, such facts are not at all incongruent with ethological thinking. One reason is that another important ethological concept, that of the "vacuum reaction," is demonstrated. As may be recalled, the vacuum reaction occurs when centrally produced action-specific energy builds up to the point where the action is run off by the organism even though the normally relevant stimulus is not observable. Thus blind babies may smile, because they are morphologically and neurologically constituted to smile, when the specific energy for smiling builds up to a certain level it is then discharged through spontaneous smiling. This spontaneous smiling, however, is relatively fleeting. And, of course, with blind babies smiling never comes to be elicited by visual, social stimuli during the second month of life, as happens with normally seeing infants (Freedman, 1966). It can, however, come to be released through stimulation in other sensory modalities (Eibl-Eibesfeldt, 1967).

The existence of more than one releaser of the smiling response, as shown by Wolff (1963) and by Freedman (1966), constitutes a phenomenon which resembles that for many fixed action patterns of lower animals. The fighting response of the male of a tropical fish, *Astatotilapia strigigena* (Pfeffer), to pick only one such case, can be elicited by several different stimuli, all of which are characteristics of an intruding and attacking male (Seitz, 1940). Any single characteristic is about as effective as any other in eliciting fighting, however, if two are present, then the elicited fighting response is twice as great. The more stimuli simultaneously present, the more intense the fighting response of the fish. Thus the intensity of an innate fixed action pattern's performance can depend not only on what sign stimuli are present, but also on how many are present. Analogously, Wolff (1963) reported that month-old babies smiled more to a nodding, talking head than to either a merely nodding or merely talking head.

However, unlike the stimuli that elicit

fighting behavior in Seitz's fish, it was found by Wolff that different stimuli had different effectiveness in eliciting the smiling response. This is also the case with many other fixed action patterns, an example being the egg-retrieving behavior of the ringed plover (Koehler and Zagalus, 1937), as mentioned earlier. Wolff observed that the bare face is more effective than a mask, a face with sunglasses, or a mask with sunglasses.

Wolff (1963) also reported evidence suggesting that the ethological concept of action-specific energy can apply to the smiling response in ways other than the existence of the "vacuum reaction." The baby, Wolff noted, must be in the proper "mood" or readiness for smiling. The smiling behavior is exhaustible by sufficiently repeated presentations of a single stimulus and then may be elicited anew either after a period of no smiling or by a new stimulus. For example, a face may be presented from seven to ten times before smiling is depressed. Then, if a mask is presented, smiling can once more be elicited, but for fewer times, perhaps five. Then, if sunglasses are added, smiling may be elicited about three more times.

The applicability of the ethological concept of action-specific energy to smiling behavior is even more clearly seen in the observed prosocial smiling of babies less than one week old (Wolff, 1963). During this age period, spontaneous smiling is seen only during states of irregular sleep or drowsiness. When smiling occurs under such conditions, there is a refractory period of five minutes or more before the baby smiles again. At this age the performance of the smiling response also has a definite relationship in interaction with the performance of other behavior patterns. For example, there is an inverse relationship between the frequency of smiling and frequency of other spontaneous behavior patterns in which the baby may engage, such as startling, rhythmical mouthing, sobbing inspirations, or stirring, according to Wolff. Similar frequency relationships between different fixed actions have also been observed in chickens by von Holst and von St. Paul (1960, 1962) in their neurophysiological investigations.

The change in the character of smiling behavior as an expression of spontaneous neurological discharge to one elicited by definite stimuli, as noted by Wolff (1963) and by

Freedman (1966), is another phenomenon that ethologists have noted in animal behavior. This is that the innate releasing mechanism (IRM) may become increasingly selective toward sign stimuli during the life of the individual. Such a process is postulated to occur in all members of the species, not in just one individual. The increased selectivity may be of either of two types: (1) narrowing of the range of stimuli evoking a particular response through the dropping out of individual stimuli, and (2) selection and strengthening of a few releasers out of a large range of potential releasers, with the result that only these and not any of the others elicit the response. The second is the phenomenon seen in social imprinting of precocial bird species, the first is the phenomenon seen when habituation to specific stimuli of the innate behavior pattern occurs or when strong negative conditioning of aversive stimuli occurs. For example, the fright behavior to predators drops out with respect to moving leaves and twigs. Or, a toad will at first snap at all small objects, but after a single unhappy experience it will avoid bees and wasps.

Hence we see that the human face becomes increasingly effective as an elicitor of the smiling response in human babies, at the same time the response becomes increasingly selective as a function of age. This is because whereas eyes alone are initially effective, greater and greater approximation to the natural human face becomes required in order to properly elicit smiling behavior, according to Ahiens (1954). Similarly, Wolff (1963) found that touching the infant's hands with his own and then patting his hands together three times in succession failed to elicit smiling until the infant was around the age of four to six weeks, when it suddenly became effective (precautions were taken to ensure practice effects were not responsible) and thereafter was effective even when the baby was fussy.

The notion of increased selectivity of the innate releaser mechanism as a consequence of the experience of the individuals of the species appears to also be applicable to smiling behavior. Ambrose (1963) pointed out that there seems to be an early sensitive period for smiling, and this sensitive period appears to be terminated by wariness of

strangers. Ambrose regards the situation as analogous to the social imprinting phenomenon found in precocial animals wherein following tendencies are terminated at the appearance of fear of strange objects. The notion of the temporal coincidence of the appearance of the fear of strangers by human babies with the ending of the sensitivity for learning primary social responses to people was proposed even earlier by Hess (1959b).

The Value of Ethology to the Study of Human Behavior

Fundamentally, it is the ethological *attitude* which is most valuable in the analysis of human behavior, rather than merely the use of the particular *terms* used by ethologists. An investigator does not need to be an ethologist or even to have had any direct contact with ethology to make behavior analyses which are congruent with ethological thinking. He merely must approach his subject with a concern for the *complete* context in which observed behaviors occur, including biological bases and adaptive function.

Ethologists have made a great many speculations on human behavior, and there have been several actual experimental investigations. For example, von Holst (1938) demonstrated that relative coordination of movement occurs in man just as it does in other animals: if two arms are moving at different speeds, one twice as fast as the other, the faster arm will make alternate long and short sweeps in coincidence with the down and up strokes of the slower arm. And, of course, psychologists have known for some time that locomotion matures in human beings (Gesell, 1947, McGraw, 1947) just as it does in animals (Carmichael, 1926, 1927, Gihmann, 1939).

Lorenz (1943) has described a relatively stereotyped motor response which occurs in humans. The touch stimuli from an insect crawling on the skin release the action of throwing it off quickly with the hand. There is both a fixed pattern component and an orientation component in this reaction. Hence it is not simply a reflex. Tinbergen (1951) has suggested that this action, though maturing relatively late, is probably innate.

The application of ethological concepts appears particularly apropos to problems of human development in both the ontogenetic

and phylogenetic sense. The behavior stereotypes of captive animals, for example, have been observed to be akin to the behavior stereotypes that can be seen in orphaned children, as reported by Klumpfinger (1950a, b). The repetition or perseveration of certain movements by hospitalized children can also be seen in home-reared children whose mother has no child care helper and is very busy with her housework or her profession (Lorenz, 1955). Maternal deprivation thus appears as a factor in the etiology of this behavior in children, just as social deprivation appears in the etiology of the cage stereotypes of captive animals.

Several ethological concepts currently are becoming increasingly important in application to human development. One such concept is that of "sensitive periods." The notion of sensitive periods in development has been utilized since 1900 by Europeans in many different fields. Even before this there were several beginnings of the sensitive period notion in the work of the early embryologists, notably Geoffroy-St. Hilaire (1822) and Darwint (1869, 1877). In biology, the Dutchman de Vries (1899, 1901, 1905) applied it to the growth of plants. He found that there was a time during which environmental conditions could influence the form taken by poppy flowers of a particular variety, after this particular developmentally linked sensitive period had passed, such environmental conditions could no longer influence subsequent morphological development, even though the development in question had not yet even occurred. In fact, de Vries himself used the term "sensitive period" to denote this phenomenon, which he also observed in the development of many other plants.

In the beginning of the development of psychoanalysis Sigmund Freud (1905) stated the notion that there are sensitive periods in the early development of children. Freud postulated that injurious events during these periods had relatively lasting effects on adult behavior. In education, the Italian Maria Montessori (1936, 1949) applied the concept of sensitive periods fully to the mental development of children. At the same time Lorenz (1935), an Austrian, applied the notion to the imprinting phenomenon in the social behavior of precocial birds.

Lorenz observed the behavior of newly

hatched geese, both in the company of the natural parents and when he presented himself to the young animals as a parental object before they had an opportunity to associate with their own parents. Because the latter animals later in life treated other human beings as fellow species members and the former animals remained with their own species as a result of having first associated with their own parents, Lorenz (1935) concluded that species recognition was "imprinted" (*Pragung*) onto the nervous system of these young during the first period of exposure after hatching.

Under natural conditions imprinting serves its purpose quite well. The first object seen is, of course, the natural parent. Furthermore, the rapid attachment of the young to the parent is necessary for the survival of the young animal. During the first days of life, the parent broods the young, protects it from predators, leads it away from dangerous situations, and takes it to food objects in the environment.

Since the early 1950s imprinting has been extensively studied in the laboratory, particularly in the United States. This work has been reviewed in papers by Moltz (1960, 1963), by Hess (1959, 1964), by Sluckin (1964), and by Bateson (1966). The results of laboratory investigation on imprinting carried out by Hess (1964) can be stated in five main points, each of which appears to make imprinting a phenomenon quite different from the association learning commonly studied by experimental psychologists.

- 1 In waterfowls there was a sharp and distinct critical period found by Hess. In the case of wild mallard ducks there is a peak of sensitivity to the imprinting process at about 16 hours after hatching in socially isolated birds, after which time the sensitivity drops rapidly. By 32 or 48 hours of age the increased fear response of the young animal appears to interfere with further imprinting capability. Similar critical periods have been found for imprinting in other birds as well. Although they are not necessarily within the first day, all of them are in the very early life of the organism.

- 2 The use of certain drugs, particularly muscle relaxants, interferes completely with the acquisition of the imprinting effect. These

same drugs do not interfere at all with the normal acquisition of a discrimination habit such as would be experimentally studied in a psychology laboratory

3 Massed practice is more effective than spaced practice. In addition, Hess discovered the *law of effort*, which states that the strength of imprinting is positively related to the amount of energy expended by the precocial hatchling bird in going to or in attempting to go to the imprinting object.

4 Primacy and recency work in a way completely different from association learning. In imprinting it is clearly the first thing that is "learned" which is retained, whereas in association learning a primacy-recency experiment will show that the animal tends to respond to the last meaningful stimulus.

5 The effect of punishment, or painful stimulation, is the opposite of what occurs in an association learning situation. This notion is of particular interest in the field of child psychology and in psychiatry. A study on this phenomenon was published by Kovach and Hess (1963).

In Kovach and Hess's investigation there are data on groups of chicks at an age close to the critical period peak of 13-16 hours after hatching, 18 hours, and at an age well beyond the critical period for imprinting, 48 hours. At each age the experimental animals were given electrical shocks while in an imprinting apparatus with a model (a "parent" object), while others received no shock in this situation. However, the animals that were shocked during the optimum period for imprinting actually followed the parent model significantly more than the control animals that did not receive any shock. The reverse was true for the chicks exposed at the age of 48 hours.

Although these results would be perplexing from the standpoint of association learning, they are not unreasonable from the standpoint of instinctive behavior and the normal survival value of such behavior, in ethological terms. If, for example, in the natural situation the young animal were to be stepped on by the parent before it leaves the nest, it would not be biologically useful to have the young avoid the parent, leave the nest, and die. If anything, there seems to be an overcompensation for any punishment associated with the

parental object since the animals receiving shock did follow better than the control animals when the initial exposure occurred during the critical period. Anthropomorphically, it is as though the animal in a painful situation depends at that moment on the parent to a tremendous degree insofar as survival is concerned, and will then seek to get even closer to the parent object.

At least one paper published in the psychiatric literature seems to tie this phenomenon to behavior in young children. Menaker (1956) relates submissive behavior in a child with an unloving, powerful, exploitative, and dominating mother to innate mechanisms of submission which prevent species members from killing each other. However, it would appear that, in the light of the research involving imprinting and shock, the child who is in an essentially punishing relationship with the parent and reacts by idealizing the parent and picturing this parent as all-powerful and loving is doing much the same thing that a chick does during the critical period when it follows a model even more closely when punished in its presence. The motor patterns involved in the two cases, of course, are different and therefore not in any sense homologous. It is not impossible that both submission and intensified affiliation can operate innately in the human child and be vital to survival. Just as there is a selection pressure for a chick or a duckling to stay with the parent under the most adverse conditions, a similar selection pressure must operate with the human child who obviously could not survive alone.

The fact that most modern societies have made provisions to give children adequate physical care may obscure the functioning of a mechanism which would bind the child to the parent during his period of dependency even when he is physically punished. As Polt (1966) suggests, it almost seems as though the normal parent-child relationship implicitly assumes that something of this sort operates. Whereas association learning would predict that when a child is chastised by the parent for an undesirable act, the child will associate the punishment with the parent as the agent of the punishment, the child in fact associates the punishment with the misdeed.

Numerous theoretical papers have at-

tempted to delineate the relationship between socialization in human infants and the imprinting phenomenon Bowlby (1953, 1958, 1960), for example, has pointed out several congruent features between the ethological findings regarding imprinting and psychoanalytic principles on the development of social attachments in human babies: the innate drive to make a "love" relationship with a parent figure, the strong influence of the individual's early love object on the selection of a love object (both sexual and parental) in adult life (a process which in abnormal cases in human beings may be carried to the point of pathological fixation), and the critical or sensitive phases of development with reference to both the organization of the motor patterns adopted and the nature of the object selected.

With regard to the notion of sensitive periods for the establishment of emotional bonds between mother and infant, several writers have postulated specific ages for primary social development to occur. Gray (1958) proposed the period of six weeks to six months, Hess (1959b) the first five and one-half months of age, Rollman-Branch (1960) the first six months, and Ambrose (1963) the age period from five to twelve weeks.

Ambrose (1963) has contended that there are good grounds for drawing an analogy between social imprinting and primary socialization in humans. On the basis of his own earlier research with the smiling response (Ambrose, 1961), he suggested that the sensitive period for supra-individual learning of the human face starts at approximately the fifth week of life and ends at approximately 12 weeks of age for family-reared infants and at approximately 18 weeks of age for institutionalized infants. The postulation by Ambrose that the location of the sensitive period depends upon the nature of the caretaking to which the child has been exposed is congruent with the idea that the end of the sensitive period for social imprinting is delayed when the sensory-social input to the organism is below normal, a notion found in some other studies of social imprinting (e.g., Klopfer, Adams, and Klopfer, 1964). The supra-individual learning of the human face, furthermore, was proposed by Ambrose as the human analogue of supra-individual learning of the species in precocial birds.

The question of whether social imprinting

exists in man has been a perennial one. This issue is certainly difficult and complex. One of the principal difficulties is that the baby cannot actually follow the parent at an early age, as is the case with precocial species which have demonstrated imprinting in primary socialization. Furthermore, it appears to many writers that primary socialization occurs in the human child before it is able to crawl.

Gray (1958) has suggested that the smiling response is homologous to the following response of young precocial birds, particularly since it ends when a fear response to strangers appears, as we mentioned earlier. The comparison between the fear response of young infants to strangers and that shown by young birds has also been made by Friedman (1961). However, it certainly is not permissible to *homologize* between avian and human species: the motor patterns of following and smiling are not the same. Besides, there is an insufficiency of cases of social imprinting in intermediate species. Also, just because there is a period of positive responsiveness and positive attachment followed by the fear reaction, this does not establish the existence of a social imprinting phenomenon in human beings, as Ambrose (1963) has rightly contended. The distress behavior evident in young chicks or ducklings already imprinted to their siblings or to another parent object may possibly reflect a searching for the lost companionship rather than fear of the new situation per se. Thus, while fear may cause incompatible response in birds which have been completely isolated socially since hatching, this may not be the case in socially maintained ones.

Other comparisons between social imprinting in birds and primary socialization in humans, however, have been suggested by Ambrose (1963). He pointed out the broad similarity between the nature of the innate releasing situations for smiling in babies and following in chicks and ducks, which are both releasing situations that involve mother objects. Not only are there close similarities in causation, in his opinion, but there is also a close similarity in function. This function is keeping the young organism close to the mother object. Whereas the young chick or duckling can follow, the human infant is utterly incapable of doing so for several months. However, the human baby's crying normally

does serve to bring his mother to him from a distance and his smiling serves to keep her present when she is already nearby. Ambrose also pointed out that another similarity between smiling in human babies and following in chicks and ducks is that both gain in response strength in the period of supra-individual learning of the species without any conventional reward such as food.

Lastly, Ambrose also postulated that the time at which fixation upon an object is possible is a better criterion for the beginning of social imprinting and the beginning of supra-individual learning of the species in human babies than is the time when learning is first evident, which Gray (1958) had proposed. This is because, as Ambrose pointed out, a bird cannot learn its parent unless it can follow, and following of the parent is impossible unless the young bird can keep it fixated. Thus commencement of visual learning, he suggested, is conditional upon the achievement of the ability to fixate an object. In line with this notion Ambrose suggested that the mother's eyes are the first object to consistently elicit visual fixation by the infant, particularly since the studies of Ahrens (1954) and others have indicated that the smiling response is initially elicited by the eyes alone. It is of interest that Caldwell (1962) has also suggested that *visual pursuit* constitutes the "following" of the parent figure by the infant.

However, the existence of these several similarities does not necessarily force the conclusion that there is actually a phylogenetic connection between the imprinting phenomenon in birds and filial attachments to parents in human infants, as Hinde (1961) has pointed out. The synapsid and diapsid reptiles, from which mammals and birds arose, have been distinct since at least the Permian period of the Paleozoic era. Therefore parental care and infant-to-mother attachment behaviors probably have evolved independently in the two groups. Hence the similarities would more accurately indicate that these behaviors constitute analogies rather than homologies, and they originate from similar selective forces in the evolutionary process.

Hinde is undoubtedly correct with respect to the development of social attachment. However, it must be pointed out that if *imprinting* is a type of learning process which, as Hess (1964) has proposed, can be applied

to a variety of situations in which specific behavior patterns are attached to a class of stimulus objects, such as food imprinting in chicks (Hess, 1962) and turtles (Burghardt and Hess, 1966), maternal imprinting in goats (Klopfer, Adams, and Klopfer, 1964), or environmental imprinting in a variety of species (as reviewed by Hess, in preparation), then imprinting is a genetically programmed learning mechanism which probably is very old phylogenetically. Indeed it seems likely that the imprinting process could have been independently seized upon by both mammals and birds for use in the development of social behavior systems, as well as in other object-response relationships. Therefore the homology, if it exists at all, would be through the phylogenetic transmission of the imprinting phenomenon and not through the phylogenetic transmission of parental care and filial attachment systems.

It can be seen that the implications regarding the effect of environmental influences during early life on the later behavior of an animal are now, and will become, increasingly important in the study of human development. Certainly the notion of stages or phases in psychological development in human beings is a very old one. The stages of babyhood, childhood, adolescence, adulthood, and old age have been enumerated for centuries. Froebel (1826) long ago declared that events in each of these stages had consequences very important for succeeding ones, a notion which has assumed since then considerable importance in the investigation of the ontogeny of behavior. To date very many sensitive periods have been suggested in the literature (reviewed by Hess, in preparation), particularly in the spheres of social-emotional behaviors and intellectual activities. The very variety of these proposed sensitive periods shows that this will continue to be a fertile field of investigation for several decades to come.

The concept of displacement activity, an extremely widespread phenomenon in the animal kingdom, has proven to be another notion of considerable interest to psychiatrists and other scholars in the area of human behavior and development. The ethological concepts of ambivalent behavior and redirected activity have already been foreshadowed for some time in the case of hu-

man behavior Freud (e.g., 1905) clearly enunciated the concept of ambivalent motivation in normal and disturbed persons. Simultaneous love and hate is the best known case of such ambivalence. Redirected behavior, particularly in the form of scapegoating, has indeed been folklore. Banging tables or desks in anger and throwing crockery are some of the most common instances of this, as is also kicking the dog or scolding the wife after a harrowing day at the office. Lorenz (1966) has described several specific examples of scapegoating as instances of redirected aggression.

Still other indications regarding displacement activities in human behavior may be found in remarks by Tinbergen (1951) and Morris (1967a). Tinbergen noted that learned activities as well as innate ones can function in this context. Examples of such learned activities include cigarette lighting and handling of handkerchief or keys, examples of innate activities having this function include head scratching and preening, often manifested in mild conflict situations. Women, for example, can often be seen adjusting nonexistent disorder in their coiffure, while men handle their beards and mustaches or cheeks and chins if clean shaven. Morris (1967a) has added to this list of human displacement activities drinking, eating, nose scratching, nose picking, ear lobe pulling, lip licking, and hand rubbing.

Makink (1936) some time ago discovered sleep functioning as a displacement activity in the avocet when in a conflict between aggression and escape. It has since then been found in several wading birds. It is interesting in this connection that there is a widespread belief among many people, including college counselors, that fatigue commonly occurs as a response to frustration, anxiety, or boredom, rather than solely as a consequence of overexertion. Tinbergen (1951) pointed out that yawning is a low intensity manifestation of sleep and is very commonly seen in moderate conflict conditions. Yawning, as most of us know from personal observation, is "catching" and it is rather amusing to find that the same phenomenon should occur in the ostrich, as reported by Sauer (1967).

Contemporary psychiatrists have used the displacement activity concept in at least three ways as a tool for approaching human be-

havior. Although each approach is somewhat different, each seems to provide a valid working *hypothesis* at the human level. Naturally, these comparisons between human and animal behaviors, just as with any comparison between different animal species, must be tested by appropriate means. This is the case even when behavior phenomena are as ubiquitous as are displacement activities. Considerable caution must be taken in regarding the human examples as actual cases of displacement activities.

The fact that many displacement activities at the animal level do not serve to maximize the survival of the individual or the species has been emphasized by Weigert (1956). She has related displacement activity to neurotic anxiety, which Freud considered to be the result of a frustrated libidinal impulse and which is, of course, basically detrimental to the individual. This interpretation of displacement activity emphasizes the nonfunctional aspect of neurotic behavior. At the same time it should be kept in mind that the conflict situation experienced by the individual may, under certain circumstances, result in the sublimation of libidinal energy into activities condoned by society, a point which was strongly made by Freud.

Another way of viewing displacement activity is that taken by Ostow (1957). After drawing some parallels between the psychoanalytic and ethological concepts of instinct, he used displacement activity as an illustration of a logical progression of development in man. Taking only the sexual instincts as an example, Ostow has hypothesized that the gratification of these instincts takes different forms during different periods of development and that the mechanism which leads from one form to another functions in the same way that displacement activity functions in lower animals. As one mode of gratification is inhibited, the instinct accepts another mode of gratification. In this way Ostow traced the sexual aims in the psychic development of humans through oral, anal, phallic, and genital stages.

The third view is that of Kaufman (1960 a, b), who suggested, on the basis of his study of ethology, that in addition to the sexual and aggressive instincts in man, there might also be an instinct for flight. Kaufman has drawn heavily on work with displace-

ment activities since many of them are the result of a conflict between aggression and fear. He pointed out that with most infaunal animals components of sexual behavior, aggression, and flight are all built-in tendencies and that the same is likely to be true of man. Further, he has advanced the notion of the usefulness of this theoretical paradigm in the treatment of patients where shyness and timidity would not have to be construed as a reaction to hostile or sexual impulses, but as a drive in its own right, that is, as a low intensity manifestation of a flight tendency.

Whereas the members of the human species have generally considered intraspecific aggression among themselves as antisocial and undesirable since it can be highly destructive, Lorenz (1966) has taken the position that it has the same positive functions as it does in infaunal animal species and, in fact, has had an important role in the formation of human society from the beginning of mankind's existence. "Aggression, far from being the diabolical, destructive principle that classical psychoanalysis makes it out to be, is really an essential part of the life-preserving organization of instinct. Though by accident it may function in the wrong way and cause destruction, the same is true of practically any functional part of any system" (Lorenz, 1966, Chap. 3, p. 48).

The observation of the various means by which aggression is dealt with in animal behavior during interactions between congeners (members of the same species) prompted Lorenz to point out the existence of several similarities in human behavior. The aggression drive, being primarily a species-preserving instinct, arises spontaneously in the organism and is subject to the same building up of specific energy and discharge that we discussed earlier for other instincts. The very same process can be seen in human beings, and Lorenz cited several instances of it. Redirection of the aggression to other objects, substitutions, and ritual ceremonies are all among the means utilized by both lower animals and human beings to deal with intra-specific aggression. Culturally derived "manners," Lorenz pointed out, have an aggression-appeasement function which immediately becomes apparent through the reaction of hostility when a person fails to observe

them. This can readily occur when people from different countries or even from different regions of the same country come into contact and are unaware that there are differences in what are considered "good manners." Similar observations have been made by a sociologist, Hall (1959, 1966).

Our discussions of aggression, smiling behavior, responses to babyishness, pupil responses (as indicators of differences between males and females in biological reaction to specific pictorial stimuli, of personality differences, and as social-communicative signals in specific situations), and displacement activities have covered only a small range of ethology's great potential in making theoretical and substantive contribution to the study of normal and abnormal human behavior. The large body of experimental data on the effects of early experience and imprinting has made it possible to draw parallels, though with considerable caution, and, in at least some respects, to test hypotheses generated by the animal work in relation to human early behavior.

Of considerable importance is the application of the methods and techniques developed by ethologists to the analysis of human behavior. For example, knowledge of the normal behavior and the normal development of behavior are cases in point. The use of schematic representations to determine whether or not sign stimuli or releasers are operating at the human level, such as in the case of the smiling response to schematic representations of the human face, allow us to come to grips with certain aspects of early human behavior.

The use of still other techniques which do not involve verbal responses may allow us to gain information regarding the development of attitudes and perceptions in the infant and growing child, either before verbal responses may be obtained or where verbal responses may not be trustworthy. Two examples of such techniques are the recording of changes in the size of the eye pupil (Hess, 1965), which has been used in a preliminary study of psychosexual development in boys and girls from the age of 5 to 18 years by Bernick (1966) and the recording of the length of visual fixation of different objects by human infants (Fantz, 1965). Both of these techniques are clearly ethological methods.

In the same vein, several studies on proxemic behavior by sociologists and anthropologists (e.g., Hall, 1959, 1966, Somei, 1959, Goffman, 1963) bear strong similarities to the ethological method of behavior study. Both emphasize the communicative (but non-verbal) function of such behavior, that is, the reaction of other individuals to specific actions that are performed. The use of space and the effects of population density are also allied to the ethological approach. In fact, Leyhausen (1965), an ethologist, is studying the effects of population density on behavior.

However, it is not only the ethological tradition of objectivity in behavior study that has importance for the study of human development. Of even greater importance are the twin concepts of the phylogenetic context of human behavior and the biological bases of this behavior. There are now many cases in which these have been or currently are applied to human behavior.

One such is the investigation of actions expressive of emotions. Indeed, Darwin (1872) was among the first to investigate this from a phylogenetic viewpoint. Other investigators, ethologists or not, have studied the form and function of expressive actions in human beings from a functional and objective viewpoint, and this area of investigation has considerable promise. Scheffen (1964, 1965), a psychiatrist, has observed the existence of various "quasi-courtship" gestures functioning as communicative signals in interactions with others and apparently on an unconscious level. These gestures were discovered through the objective recording of the motor actions and body postures of participants in interpersonal situations and not through introspection or verbal interviewing. Leg crossing, preening movements, sitting back or leaning forward, and arm folding were found to be among such movements and to be useful in establishing rapport and communication in psychotherapeutic situations. Blurton Jones (1967) has studied three- to five-year-old nursery school children with respect to facial and bodily motor expressions and the specific responses which these elicit from others. Wickler (1967) has made a preliminary comparison of sociosexual signals in man and other primates.

A frankly biological approach to human behavior may be found in genetics. This is a

very young field that promises to become extremely fertile, particularly when the ethological premise of the biological bases of behavior is accepted without racist handicaps. In my own unpublished research I have found a strong and highly consistent correlation between eye color and modes of perception and personality. Blue eyes were associated with form dominance in perception and a scientific attitude, whereas brown eyes were associated with color dominance in perception and a nonscientific attitude. The genetic bases of this obviously could be studied.

The significance of the phylogenetic viewpoint in the consideration of human behavior is highly apparent in Lorenz's *On Aggression* (1966): "all specifically human faculties, the power of speech, cultural tradition, moral responsibility, could have evolved only in a being which, before the very dawn of conceptual thinking, lived in well-organized communities. Our prehuman ancestor was indubitably as true a friend to his friend as a chimpanzee or even a dog, as tender and solicitous to the young of his community and as self-sacrificing in its defense, aeons before he developed conceptual thought and became aware of the consequences of his action" (Chap. 13 p. 245). Also, Lorenz asserted, "if, in the Greylag Goose and in man, highly complex norms of behavior, such as falling in love, strife for ranking order, jealousy, grieving, etc., are not only similar but down to the most absurd details the same, we can be sure that every one of these instincts has a very special survival value, in each case almost or quite the same in the Greylag and in man. Only in this way can the conformity of behavior have developed" (Chap. 11 p. 218). These similar behaviors in the Greylag Goose and in man, Lorenz emphatically stressed, arose through convergence and not through common inheritance. Such convergence supports even more strongly the notion that these behaviors have highly important species-survival functions.

In closing, it would seem that the most significant contribution of ethology to the study of human development, in both the phylogenetic and ontogenetic senses, is the recognition that man is a biological organism, and that he has an evolutionary history. The present-day members of the species of man have an ancient repertoire of behaviors.

From the ethological point of view, the human infant is not a completely naive being, but possesses a legacy of potential behavior patterns which at one time assured the survival of the organism even without the aid of social learning or customs. Some of these innate behavior patterns involve elements of sexual behavior, aggressive behavior, and innate social responses. Recognition of these as part of our heritage is important because, in terms of man's evolutionary history, we are not at all far from the time when there were no widespread cultural influences upon our behavior. Without our built-in behaviors, we, as a species, simply could not have managed to survive for a million years.

Indeed, as Desmond Morris (1967a) has suggested, man needs to face up to the accumulated genetic legacy of his whole evolutionary past, and as a result he may be "less worried and more fulfilled." It is the realization that these potential, genetically programmed behaviors are present and that many of them must be channeled into quite different directions in our present-day civilized world, which may make the greatest contribution toward an approach to the problems of the human species and may have a tremendous impact on the search for mental health as

well as a fuller understanding of human behavioral development. In this connection Morris (1967a), in stating that basic biological changes rather than simply acculturation have been primarily responsible for the development of uniquely human behavior from its original primate form (one example is the incest taboo), has stressed his belief that "our unbelievably complicated civilizations will be able to prosper only if we design them in such a way that they do not clash with or tend to suppress our basic animal demands."

This, of course, presupposes that we actually do succeed in knowing just what our basic animal needs are. To assume, for example, that aggression is solely the result of bad training and environment is to close one's eyes to the evolutionary usefulness and possible biological survival value of aggression, factors which surely must have a place in the make-up of man, as they do in all other animal organisms. If in this case alone the theoretical viewpoint becomes one in which aggression, when properly directed, is recognized as a useful biological consequence of man's inherent constitution, it would seem that ethology will have made a major contribution to the field of human behavior.

2. Genetic Influences on Behavior and Development

GERALD E. McCLEARN

The genetic data and principles most obviously relevant to problems of behavioral development are those that constitute the area of developmental genetics. The purpose of this chapter is to outline developmental genetics in general terms and to describe research that explicitly demonstrates genetic influence on behavioral development. However, the discussion of developmental genetics requires some acquaintance with concepts from the areas of transmission, quantitative, molecular, and physiological genetics. The first portion of the chapter constitutes a brief presentation of basic principles from these fields that are important for later discussion.

MENDELIAN RULES AND CONCEPTS

The origin of the modern field of genetics is generally traced to the discovery by Gregor Mendel in 1865 of certain "laws" that seemed to characterize the mode of action of hereditary factors, and the manner in which they are transmitted from one generation to the next. The publication of these laws in 1866 caused no immediate stir in the biological world, and it was not until 1900 that Mendel's work was "rediscovered" and a period of intensive research was initiated. In the early years, much research was devoted to assessing the generality of the Mendelian laws. This generality was found to be very great indeed, with respect to both the variety of characteristics that could be shown to be describable in Mendelian terms and the variety of organisms in which the laws could be demonstrated.

Transmission Genetics

It was not until some time later that evidence concerning the physical nature of the

hereditary material became available, so Mendel's laws were formulated in terms of hypothetical elements. These elements were named "genes." Each individual organism was assumed to have two of each gene, with one member of this pair of genes contributed by the maternal parent, and the other by the paternal parent. A gene can exist in two (or more) alternative states, called *alleles*. Two types of conditions can be described for any given individual with respect to a particular gene pair. Given the allelic state of the gene from one parent, that from the other parent must be either the same or different. If the two allelic states are the same, the individual is described as *homozygous*, if the two allelic states are different, the individual is described as *heterozygous*. Now, if we characterize one possible allelic state of a gene as A and the other as A', it can be seen that there are two homozygous states, AA and A'A', and one heterozygous state, AA'. These are descriptions of the *genotype* of the individual with respect to this particular gene pair.

A major conceptual development was the distinction between genotype and phenotype, or the observed characteristics of the individual. There is a relationship, causal and directional, from genotype to phenotype, but the relationship is not perfectly isomorphic. In different cases, different relationships of phenotype to genotype were discovered. Figure 1 illustrates several of the relationships that may occur. Genotypes are shown along the abscissa with the ordering of the genotypes and the spacing between them based upon the number of A' alleles present. The ordinate displays the phenotype under consideration. If the phenotypic value of the heterozygote AA' is exactly halfway between

Fig 1 Several different types of relationships of phenotype to genotype

the values of the two homozygotes, the system is *additive*. If the heterozygote has a phenotypic value indistinguishable from that of one of the homozygotes, *dominance* is said to exist, and the allele of the homozygous parent from which the heterozygote is not distinguishable is described as being *dominant* over the alternative allele. Intermediate situations, in which one allele is partially dominant over the other, are also possible. In such cases the heterozygote lies somewhere between the half-way point and one of the homozygotes.

Each individual begins life as a single cell, which is formed by the union of two gametes, the ovum, supplied by the mother, and the sperm, provided by the father. In the process of formation of the gametes, only one of each

gene pair is included. In Fig 2 three individuals are represented. Each individual is shown as a square, with the genotype written within the square. The phenotype is represented by the presence or absence of hachures. The A allele is shown as dominant over the A' allele. The process of gamete formation is indicated by the dashed lines and the resultant gametes are shown as small circles, each with a single allele designated. (Each gamete will actually receive many genes—one from each autosomal gene pair the parent organism contains—but our present discussion concerns only a single locus.) AA individuals can produce only A gametes, and A'A' individuals can produce only A' gametes. The heterozygote AA', however, can generate both A and A' gametes.

Fig 2 Gamete formation

The process by which these alternative alleles are distributed to gametes appears to be a random one, with equal numbers of each type of gamete being produced. Note that two individuals that are alike phenotypically, $A'A'$ and AA' , differ in the types of gametes that they are capable of producing.

Now let us assume a mating between two of the heterozygous AA' individuals. Each will produce equal numbers of A and A' gametes, which will unite at random. The situation is represented in Fig 3. Gametes from parent 1 are shown in the columns, gametes from parent 2 are shown in rows. The four cells of the table represent the four possible genotypes that can arise from such a mating. In genotypic terms, there are three possibilities: AA , AA' , or $A'A'$. Phenotypically, there are only two outcomes: "hatched" and "nonhatched." The ratio of stippled to nonstippled is three to one. This is the classic Mendelian ratio to be expected in offspring between two heterozygous individuals when there is complete dominance.

Other matings would provide other results. Consider, for example, the mating of an AA with an AA' individual. Figure 4 shows the possible outcomes. The outcome of yet other matings can be easily described. Matings of AA with AA will yield only AA offspring. Matings of $A'A'$ with $A'A'$ will give only $A'A'$ offspring. Now, in three of the mating types mentioned, AA offspring can result. An AA

Fig 3 Possible offspring genotypes resulting from random union of gametes from two heterozygous (AA') parents

Fig 4 Possible offspring genotypes resulting from random union of gametes from one homozygous (AA) and one heterozygous (AA') parent

offspring of mating AA with AA' individuals will necessarily have received one of its A alleles from the AA' parent. That A allele has been in residence with an A' allele during the life of this heterozygous parent. On the other hand, an AA offspring of a mating of an AA with an AA individual will receive A alleles that have only been in the company of other A alleles in the previous generation. Yet these two types of AA offspring are indistinguishable phenotypically, as well as genotypically. The alleles are not influenced by association with a partner of a different type.

Another extremely important Mendelian principle involves the consideration of the segregation of more than one gene pair at a time. Assume that, in addition to the gene pair $A-A'$, we have another gene pair $B-B'$. The rule of independent assortment refers to the fact that in gamete production the "selection" of a particular member of one gene pair does not influence the (random) selection from another gene pair for inclusion in the same gamete. A double heterozygote individual, $AA'BB'$, would therefore produce gametes AB , $A'B$, AB' and $A'B'$ in equal quantities. Operation of this rule is subject to some restrictions, which will be described later.

The traits to which the simple and basic Mendelian rules can be applied most directly are dichotomous traits, in which the individual may be unambiguously assigned to one

or another group. This situation is most frequently encountered in the case of rare abnormalities, although some "single-gene" conditions determine traits which fall in the normal range of variability. With human subjects, the classical method of studying such situations involves examination of family pedigrees. Clear-cut dominance or recessivity is frequently revealed by the pattern of transmission from one generation to the next. If a rare trait is determined by an allele that is dominant over its partner, affected individuals appear in each generation, and about half of the offspring show the characteristics. There is an easily understood explanation of this typical pattern. In the case of a rare condition, the affected individual probably will be heterozygous because, if the condition is rare, the alleles will be rare, and the likelihood of two such rare alleles combining in one individual will be remote. The affected individual, usually married to a phenotypically normal partner, can produce only two types of gametes with respect to this gene pair: one-half of his gametes will contain the dominant, trait-producing allele, the other half will contain the "normal" recessive allele. All of the alleles provided by the normal parent will be of the normal "recessive" variety. Therefore half of the offspring of one affected individual will receive only recessive alleles from each parent, whereas half will receive a recessive allele from the normal parent but the dominant allele from the affected parent.

In case of a recessive characteristic, the individual who displays the characteristic must be homozygous for the recessive alleles. An affected individual may appear in the progeny of the mating of two normal parents because in each of them the effects of the recessive allele are masked by the presence of the dominant "normal" allele. Since each of the parents can produce two types of gametes in equal number, the probability of the recessive alleles uniting is equal to $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$.

The principles that yield these outcomes are, of course, probabilistic ones, and pedigrees departing considerably from these "ideal" types are encountered in practice. Thus, simply by chance, some families consisting of four children from the mating of two heterozygous parents will have no affected individuals, others may have one, two, three, or four.

Single Genes and Behavior

A number of traits are known, both in animals and human beings, in which single genes have important influence over behavioral characteristics. Probably the best known of these conditions is phenylketonuria, or phenylpyruvic idiocy. This condition was first described as an etiological entity by Folling in 1934. Individuals homozygous for the recessive alleles suffer from a metabolic abnormality, to be described in more detail later, and, often but not always, they suffer from a severe degree of mental retardation.

A condition known as Huntington's chorea provides an example of a trait inherited as a dominant. This condition is characterized by the onset of neural degeneration in adulthood and the development of psychotic behavior.

Ability to taste a substance called phenylthiocarbamide is also dependent upon a single gene pair. Individuals possessing one or two of the dominant alleles find the substance to be extremely bitter. Individuals homozygous for the recessive allele find it to be tasteless.

Animal research provides many examples of single gene pair influence on behavior. A whole series of conditions bearing names such as Shaker, Jerker, Pinouette, Fidget, Jittery, Trembler, and Reeler have been described in mice. These conditions variously involve vestibular or neural defect, and they are characterized by head shaking, body trembling, and difficulties in locomotion and maintaining balance (see Gruneberg, 1952). The albino gene in the mouse, which can be easily studied because of its obvious effect upon coat color, has been shown also to have effects upon performance in water escape learning (Winston and Lindzey, 1964), activity, and emotional responses (DeFries et al., 1966).

A single gene pair in fruit flies has been shown to affect mating behavior (Bastock, 1956), and a complicated series of behavioral responses involved in removal of diseased larvae by honeybees has been shown to be under the influence of two gene pairs (Rothentubler, 1964). Worker bees homozygous for the recessive alleles of each of these gene pairs will both uncapped the cells of the diseased larvae and remove them from the nest. The presence of a dominant allele of one of the gene pairs results in the failure to remove the diseased larvae after uncapping, a dominant

Fig 5 Normal human chromosome complement Female on left, male on right (a) Photomicrograph (b) Arrangement of chromosomes into standard karyotype arrangement The sex chromosomes are shown in the right-hand column of each karyotype display The two X chromosomes of the female are shown in the top row, the single X of the male is also shown in the top row, and the small Y chromosome is shown below it in the bottom row The other chromosomes, the autosomes, are arranged by pairs in order of descending size (Furnished by Professor A Robinson)

allele of the other pair results in the failure to uncap

The preceding are examples of major gene effects on behavioral phenotypes As we shall see later, more complicated models are required to account for many quantitatively distributed traits of particular interest to behavioral scientists where major gene effects are not present Nevertheless, the demonstration of the operation of the basic laws in behavioral phenotypes permits us to proceed to the more complex formulations with confidence

CHROMOSOMES PHYSICAL VEHICLES OF THE HEREDITARY MATERIAL

The first insight into the physical nature of the genes came through observations of parallels between the rules governing Mendel's hypothetical elements and the actions of small bodies within the nucleus of cells These small bodies were found to stain selectively under certain conditions and were therefore named chromosomes Like Mendel's elements, the chromosomes exist as paired entities During

gamete formation, each gamete receives only half of the total number of chromosomes, one of each pair Ingenious researches provided evidence that the chromosomes were indeed the physical vehicles of the genes, and that the genes were linearly arranged along the length of the chromosomes Each gene pair has a relatively fixed position, or *locus*, on a particular chromosome The number of chromosomes is generally constant within the cells of an organism and across organisms within a species Species differ from one another in chromosome number, however, the number provides no clue to phyletic status Mice possess 20 pairs, crayfish 100 pairs, fruit flies (*Drosophila*) 4 pairs, and man 23 pairs Figure 5 shows a normal human chromosome complement Figure 5a shows the chromosomes as seen in the microscopic preparation, part b presents the same chromosomes arranged in groupings according to size and other characteristics Because of the stage at which the cells were prepared for examination, each individual member of the chromosome pair appears doubled This is because

it was in the process of replication at the time of preparation

Linkage

The linear arrangement of genes on chromosomes accounts for a restriction of the free operation of the law of independent assortment described earlier. As long as the two loci under consideration are on different chromosomes, the law of independent assortment holds. If the two loci happen to be on the same chromosome, then there is a tendency for the alleles to assort together during gamete formation. This *linkage* is not complete and absolute, however. Gamete formation is distinguished by a process called *meiosis*. During meiosis, the two members of a chromosome pair line up adjacent to one another. At one stage of meiosis, they may cross over one another and, with breakage and reuniting of the broken ends, may exchange homologous portions. For example, let us suppose that we are concerned with three particular loci out of the very many loci that will occupy the length of the chromosome. Let us assume that an individual received a chromosome from his father which contained an A', B, and C' allele, whose loci are arranged as shown in Fig. 6. Assume further that the maternal chromosome contained alleles A, B', C, at these loci. The individual in question is therefore heterozygous for the three loci. The alleles will not randomly and independently appear in the gametes formed by this individual. If a gamete contains A', the probability is greater than one-half that it will also contain B. Crossing over, and the exchange of genetic material, is a function of the linear distance between loci. Therefore crossing over would, in our hypothetical example, occur

much more frequently between the B and C locus than between the A and B locus. That is, the contingent association of the latter would be much higher than that of the former pairs of loci.

It is important to note that linkage of two loci does not imply a permanent correlation of the traits determined by these loci in the population. Over a sufficient time period, crossing over will have occurred often, and the association of, say, A with B, of A' with B, of A with B', or of A' with B' will simply be products of the relative frequencies of these alleles in the population's gene pool. The constraint of linkage therefore has implications for the contingent transmission of alleles affecting different traits over a few generations, but it does not cause a permanent correlation between these traits in the population after many generations of random mating.

Sex Linkage A special kind of linkage relationship is attributable to the chromosomal basis of sex determination. Two kinds of chromosomes may be distinguished. In the *autosomes*, which in man number 22 pairs, the individual members of the pairs appear to be equal, both in terms of microscopic appearance and also in terms of having the same loci arranged in the same order. In the males of man, mouse, fruit fly, and many other organisms, there is an inequality of the members of one chromosome pair, the *sex chromosomes*. The longer of the sex chromosomes is called the X chromosome, and the shorter one the Y chromosome. Females possess two X chromosomes. Males, on the other hand, possess one X and one Y chromosome. It appears that the small Y chromosome contains no or very few loci homologous to those on the X chromosome. Thus a recessive allele on the X chromosome of a man cannot have its effects masked by the presence of a dominant allele on the Y chromosome. In other words, the concepts of homozygosity and heterozygosity do not apply to sex-linked loci in males. This situation produces some interesting patterns of transmission. Note that females can only produce X-bearing ova. Males can produce both X-bearing and Y-bearing sperm. A male will therefore have received his only X chromosome from his mother, and he cannot transmit it to any son.

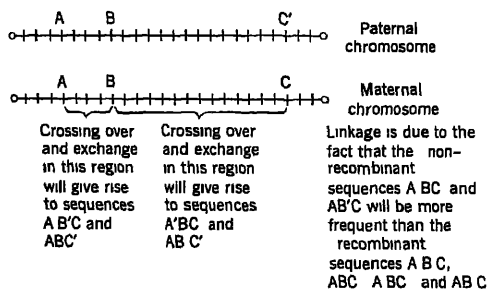

Fig. 6 Gene linkage and crossing over

Red-green color blindness is a classic example of a sex linked trait in man. Women who are homozygous for the recessive alleles cannot distinguish the two colors readily or at all. Heterozygous women or those homozygous for the dominant allele have normal color vision. A male has only one allele, and if it be the dominant, color vision will be normal, if recessive, color vision will be defective. As a consequence of these relationships, certain regularities ensue. All normal visioned daughters of color blind men must be heterozygotes. If they marry normal color visioned men, one-half of their sons, on the average, will be color blind. A color blind woman will have received one recessive allele from her father, who must therefore be color blind, and one from her mother.

One characteristic of sex linked conditions is that the frequency of occurrence is much greater in males than in females. The reason for this inequality in incidence can be readily understood. Let p represent the proportion of the dominant allele in the population, and q represent the proportion of the recessive allele. If mating is at random, the probability of a recessive allele combining with another recessive allele in a female child is $q \times q = q^2$. For males, however, the frequency will simply be equal to the population frequency, or q . Since these values are stated as proportions, q^2 is much smaller than q . An extension of this reasoning permits the estimation of the number of heterozygotes or "carrier" women in the population. The probability of two dominant alleles uniting is p^2 , and the probability of heterozygote combinations is equal to $2pq$. The frequency of color blind males in the population, which, as we have seen, estimates q directly, is approximately .08. By subtraction, p must equal .92, and p^2 therefore is equal to .85, which represents the number of homozygous normal females, $2pq$ is equal to .15, which is the frequency of "carriers," and q^2 , the frequency of color blind women, is less than .01.

Chromosome Anomalies and Behavior

Ordinarily, in the process of gametogenesis, the duplication of chromosomes in a cell, and their subsequent allocation to daughter cells, is accomplished with great precision. Occasionally, however, mistakes occur which result in the formation of gametes with ab-

normal chromosomes or an abnormal number of chromosomes. One such error is *nondisjunction*. In nondisjunction, both chromosomes of a given pair go to the same daughter cell, with the result that one of the gametes formed will have the normal complement plus one extra chromosome, whereas the other gamete will have the normal complement minus one chromosome. If an egg which has an extra chromosome due to nondisjunction is fertilized by a normal sperm, the resulting zygote will have the normal pair of chromosomes for all except one, which will be present in triplicate. This condition is known as trisomy. Similarly, an egg lacking one chromosome, fertilized by a normal sperm, will give rise to a condition known as monosomy in which one chromosome is present only in a singlet. Similar results occur, of course, when abnormal sperm fertilize normal eggs.

Autosomal Trisomy The well-known and intensively studied syndrome of mental retardation known as Mongolism or Down's syndrome was one of the first human syndromes in which a chromosomal anomaly was described. Lejeune et al. (1959) and Jacobs et al. (1959) almost simultaneously reported that mongoloid individuals possessed 47 instead of the usual number of 46 chromosomes. Detailed analysis revealed that the extra chromosome was a small one with cytological features that identified it as number 21. This discovery illuminated greatly the etiological picture of Down's syndrome, which had become a confusing assemblage of contradictory evidence concerning various genetic hypotheses and hypotheses about environmental causal factors. The "accidental" nature of nondisjunction renders irrelevant speculation over whether the trait is inherited as a dominant or as a recessive. Similarly, since the critical event has occurred during gametogenesis, theories implicating environmental factors which occur during gestation are also seen to be beside the point. However, there are two links in the etiological sequence that remain to be clarified. The first is the circumstance or circumstances that cause the "accident" of nondisjunction, the second concerns the reason why excess genetic material causes the developmental abnormalities.

Regarding nondisjunction, it has been well

established that the risk of bearing a child with mongolism increases markedly with maternal age. Since the sex cells of the human female are partially formed before birth, rather than being continuously produced throughout life, it seems reasonable to speculate that the age dependent risk function reflects the fact that the gametes of older females have been exposed to environmental forces, as yet unknown, for a longer period of time than have those of younger females, with a corresponding increased likelihood of aberration. The nature of the relevant environmental factor is as yet unknown, although some recent work (Nichols et al, 1962) has suggested the possibility of a viral infection being an important factor in chromosome breakage. The possibility of an infectious determinant of nondisjunction is also suggested by the epidemiological studies that have shown Down's syndrome births to occur more closely in space and time than would be expected on the basis of a random occurrence hypothesis (Collman and Stoller, 1960, Hennrichs et al, 1963).

With respect to the problem of the mechanism whereby extra hereditary material causes abnormality of development, it has been proposed that overproduction of enzymes is the critical factor, and research on this point is actively in progress (Herring et al, 1967, also see Lejeune review, 1964), but without definitive results at present.

Trisomy probably occurs with respect to all autosomes, but it is evidently lethal in most cases. For example, one recent study (Cari, 1967) examined 227 spontaneous abortions for evidence of chromosome anomaly. Fifty of the abortuses were found to have an anomaly, and 27 of these were trisomies. This incidence of chromosome abnormality in abortuses is more than 50 times as high as that in infants born alive.

Two other autosomal trisomic conditions, trisomy D and trisomy E, have been described in live-born infants. Both of these conditions involve extensive abnormalities and poor prognosis for survival. Trisomy D (the triplet chromosome is not exactly identifiable, but is one of group D, nos 13-15) involves deficient telencephalic development, absence of the olfactory tracts, and small or absent eyes. Trisomy E involves cardiac and kidney defects and hypertonicity. See Smith

(1963) for a review of these conditions.

Autosomal monosomies have not been described in man, suggesting that the absence of one member of an autosomal pair is highly lethal. The absence of autosomal monosomies in the study of abortuses already cited (Cari, 1967) suggests that the lethality of the condition is manifested at a very early stage of development.

Other Autosomal Anomalies Another type of chromosomal accident arises from the occasional exchange of material between non-homologous chromosomes. Through this means, a chromosome is sometimes formed with extra material from another chromosome pair or with part of its original material exchanged with material from a different chromosome pair. When a gamete possessing such an abnormal chromosome is fertilized by a normal gamete, the resulting zygote will be deficient with respect to some hereditary material and will possess an excess of other hereditary material. A translocation of this nature was suspected when a patient with Down's syndrome was shown to have the normal number of 46 chromosomes, rather than 47 (Polani et al, 1960). Detailed study of the chromosome complement showed that one chromosome was longer than usual. The interpretation was that this larger chromosome had extra chromosomal material from chromosome number 21 attached to it. It therefore appears that Down's syndrome may be caused by an excess of a portion of chromosome number 21.

Still another type of chromosome anomaly involves the deletion of some chromosomal material. Such a condition appears to underlie the clinical syndrome known as "*cr-du-chat*". This syndrome involves quite severe mental retardation, and the affected children are characterized by a cry that is very similar to that of a cat or kitten—thus the name. A number of cases have been reported since the original observation by Lejeune and co-workers (Lejeune et al, 1963, Macintyre et al, 1964, Schmid and Vischer, 1967, Itoh and Gotoh, 1967, Schlegel et al, 1967).

Affected individuals have been found to lack one end of one member of the chromosome number 5 pair.

Sex Chromosome Trisomy Klinefelter's syndrome is a condition of incomplete sexual development in ostensible males which is

very often associated with mental defect. The syndrome is probably a heterogeneous one composed of different etiological entities. Many of the affected individuals have been shown to have 47 chromosomes, with the normal number of paired autosomes and a sex chromosome constitution of XXY.

Another trisomy involving the X and Y chromosomes has recently been found to have interesting behavioral implications. Hauschka et al (1962) described a case of an XYY male who was asymptomatic. A short while later Ricci and Malacarne (1964) described an XYY individual with deficient mental development. Jacobs et al (1965) conducted a survey of mentally retarded male patients who had violent, dangerous, or criminal propensities, in a maximum security prison hospital. They found 7 of the 197 examined patients to have an XYY sex chromosome complement. This incidence is greatly in excess of that to be found in the normal population, and suggests that the presence of the extra Y may relate to the degree of mental retardation and to the aggressiveness characteristic of these inmates. These individuals are also unusually tall. Price and Whatmore (1967) performed follow-up observations on these patients and found them to differ from control inmates who had a normal sex chromosome complement in the following ways:

1. The record of XYY males revealed considerably fewer crimes of violence against persons than did those of the XY males. The XYY violence was evidently more directed against property than persons.

2. The behavior disturbance of the XYY inmates had an earlier onset than that of the XY inmates.

3. Siblings of XYY inmates were significantly less likely to have antisocial records than siblings of XY inmates.

Another recently reported case (Forssman, 1967) conforms to the general picture in that extreme aggression became apparent at about age 10, and Stanford-Binet IQ was 69 at age 15. This child was also unusually tall and suffered from epileptic seizures.

XXX individuals have also been described, but as yet no consistent clinical picture has emerged (Day et al, 1964).

Sex Chromosome Monosomy Although

monosomy of autosomes appears to be incompatible with life, one of the possible sex chromosome monosomies is found. Individuals with only a single Y have not been found, but the single X condition (symbolized XO) gives rise to Turner's syndrome, which involves sexual infantilism in presumptive females. In addition to the abnormalities of sexual development, Turner's syndrome patients have been found to suffer from a specific form of perceptual-cognitive deficiency. Money (1963, 1966) has described a series of tests measuring spatial ability in which Turner's patients are strikingly inferior to normal control individuals.

Other Chromosome Anomalies Polysomies of higher order than trisomy have been identified with respect to the sex chromosomes XXX, XXYY, XXXYYY, and XXXY. Individuals have been described, for example. Mosaics have also been identified in which some of the body cells have one chromosome complement, others have a different one. For example, XO/XX, XO/XY, XX/XY and even the triple mosaic of XO/XY/XXY have been described with respect to the sex chromosomes. Mosaicism has also been implicated in Down's syndrome in a case (Clarke et al, 1963) in which some cells were found to be trisomic and others normal. Other mosaics for Down's syndrome have been described, and, in some but not all, the mosaic cases have been shown to have higher IQs than the typical case (Polani, 1963).

QUANTITATIVE GENETICS

It is very important to appreciate the fact that the demonstration of a single locus effect, as in phenylketonuria, does not imply that the normal allele for that locus is exclusively responsible for determining the normal expression of the character. It is appropriate to regard the defect as due to the occurrence of the genetic block at one of the many possible crucial points in a multiplex system. In the absence of a block of this kind, the normal expression of variability in a population is attributable to the joint action of a number of loci, each of which makes a small contribution to the total phenotype. Investigation of these complexly determined phenotypes constitutes the field of genetics called polygenic, multiple factor, or quanti-

Fig 7 Absence of epistasis Effect of A locus genotype on phenotype is independent of B locus genotype

tative genetics It is easy to see that the basic applicable model is a binomial one, since each (autosomal) locus is present in duplicate. If we then assume a number of loci, each with two allelic states, each with an equal small individual effect, each acting additively, the distribution of the phenotype under consideration would be simply $(A + A')^{2n}$ where n = the number of loci.

This very simple picture becomes complicated, of course, if dominance exists at any of the loci. In addition to dominance, which may be regarded as a form of intra-locus interaction, in polygenic systems we must be concerned with inter-locus interaction, usually termed in this context *epistasis*. Essentially, epistasis refers to a situation in which the relationship of the phenotype to the genotype at one locus is dependent upon the genotype at a different locus. Consider Fig 7, for example. Phenotype is plotted against locus A genotype, with locus B genotype as a parameter. With the lines separated only for graphic convenience, this hypothetical example shows that the effectiveness of the A locus in influencing the phenotype is independent of the genetic condition at the B

locus. Figure 8 represents a situation in which the effect of the A locus is unaffected by the B locus if the genotype is B'B' or BB', but the A locus has no influence at all if the genotype is BB. A specific illustration of this type of inter-locus interaction is the effect of the albino gene in mice. A number of coat color loci have been described, some of which determine the type of pigment, some of which determine the location of the pigment along the hair, and so on. None of these loci have any phenotypic effect, however, in the presence of a homozygous recessive condition at the albino locus.

The analysis of a polygenically determined system cannot be accomplished by the classical methods of pedigree analysis, since the effects of the individual genes are assumed to be small. Statistical analysis is therefore required, and a number of models and techniques have been developed to estimate various genetic parameters from statistics. A key concept in quantitative genetics is *heritability* (Lush, 1940), which is defined in terms of various ratios.

If we may assume that genotype and environment are uncorrelated, the total pheno-

typic variance (V_P) in a population may be regarded as the sum of genetic variance (V_G) plus environmental variance (V_E). For only one locus,

$$V_P = V_G + V_E$$

where the genetic variance itself may be subdivided into an additive portion, arising from the average effects of genes, and a dominance portion. When more than one locus is involved, another source of genetic variance, arising from epistatic interactions among loci, must be considered

$$V_P = V_A + V_D + V_I + V_E$$

where V_A is the additive genetic variance, V_D represents intralocus interaction, and V_I represents interlocus interaction. It is often convenient to combine intralocus and interlocus interaction in a nonadditive variance term

$$V_P = V_A + V_{NA} + V_E$$

In a broad sense, heritability is sometimes defined as the proportion of total phenotypic variation which is ascribable to genetic sources V_G/V_P . However, for many purposes, both in description and prediction, a more narrowly defined ratio, V_A/V_P , is employed. To distinguish these two, Falconer

(1960) proposed a usage that describes the second as heritability and the first as degree of genetic determination.

It is worth repeating and emphasizing at this point that the key concept of heritability explicitly and necessarily involves the simultaneous consideration of both genetic and environmental determinants. With this formulation, an attempt to describe a trait as being "genetic" or "environmental" in origin is seen to be meaningless. It is also important to know that the heritability estimate obtained from a particular set of operations, such as those to be described shortly, is not an eternal, fixed value of the trait. Depending simultaneously upon environmental and genetic variance sources, the heritability will change as a given population is subjected to different environmental circumstances, or as its genetic composition changes. Thus a heritability value refers to a given trait in a given population at a given time in a given environment.

Human Research

In research on quantitative inheritance in man, the principal techniques have involved studies of the resemblance of relatives, including twins, and of foster children.

Fig 8 Epistasis Effect of A locus genotype on phenotype is dependent upon B locus genotype

Resemblance of Relatives The assessment of the phenotypic correlation that exists among relatives provides certain estimates of the genetic determinants underlying the phenotype. In a population which is in a "Hardy-Weinberg" equilibrium, the relative proportion of A'A', AA', and AA genotypes will be p^2 , $2pq$, and q^2 . Essentially, the conditions that must be satisfied for the population to be in this equilibrium state are that mating be random with respect to the traits influenced by the genes under consideration, that there be no differential reproductive advantage to any of the genotypes of the locus under consideration, and no significant migration into or out of the population. Admittedly, these requirements are likely to be violated in real populations, but a consideration of the ideal case forms a basis for the discussion. If we assume furthermore that the alleles of the locus act additively, and that there is no environmental effect on the trait in question, we may arbitrarily set the phenotypic values of the genotypes as

$$AA = 0, \quad AA' = 1, \quad A'A' = 2$$

Then, since our frequencies are in terms of proportions, the mean of any generation will be equal to

$$\frac{p^2(2) + 2pq(1) + q^2(0)}{2p^2 + 2pq + 2p(p+q)}$$

but

$$p + q = 1, \quad \text{so the mean} = 2p$$

If the population is in equilibrium, as we have assumed, then this mean value will be characteristic of all generations.

Similarly, the variance of a generation will equal $p^2(4) + 2pq(1) - (2p)^2$, which simplifies to $2pq$.

The covariance can be obtained by the following consideration. Table 1 gives frequencies of association of one parental (say, maternal) and offspring genotypes, and indi-

Table 1 Relative Frequencies of Offspring Genotypes for Mothers of Different Genotypes

Maternal Genotype	Offspring Genotype		
	A'A'	AA'	AA
A'A'	$p^3(4)$	$p^2q(2)$	—
AA'	$p^2q(2)$	$pq(1)$	$pq^2(0)$
AA	—	$pq^2(0)$	$q^3(0)$

cates the arbitrarily assigned cross-product values. The frequency values in the body of the table were derived from considerations of the mating frequencies and of the relative proportion of the genotype of children from the different mating types. For example, A'A' women, who are p^2 of the population of women, may marry either A'A', AA', or AA men who are present in the population in the frequencies p^2 , $2pq$, q^2 . Then, if mating is at random with respect to this locus, the matings of A'A' women with A'A' men will occur with a frequency of $(p^2)(p^2) = p^4$. Similarly, A'A' by AA' matings will occur with a frequency of $(p^2)(2pq) = 2p^3q$, and that of A'A' by AA with a frequency of $(p^2)(q^2) = p^2q^2$. If we assume that all matings are equally fertile, and that all children are equally viable, the proportion of children from each mating type will equal the frequency of the mating type. Thus A'A' by A'A' matings will produce p^4 of the next generation. All p^4 of the children will be A'A'. Of the mating type A'A' by AA', one-half, or p^3q , of the children will be A'A' and the other p^3q will be AA'. Of the mating type A'A' by AA, all p^2q^2 children will be AA'. Thus A'A' mothers will have A'A' children in the relative frequencies of $p^4 + p^3q = p^3(p+q) = p^3$, and AA' children in the relative frequencies of $p^3q + p^2q^2 = p^2q(p+q) = p^2q$. Similar computations for other mating types provide the other entries in Table 1. The covariance will equal $p^3(4) + 4p^2q + pq - (2p)^2$ where the last term is the correction for the mean. This expression simplifies to pq .

The correlation between offspring and mothers (or fathers, if the locus is an autosomal one) will equal the ratio of the covariance to the geometric mean of the variances, or

$$\frac{pq}{\sqrt{(2pq)(2pq)}} = \frac{pq}{2pq} = \frac{1}{2}$$

It may be noted that this formulation is only correct as long as both alleles are present in the population, that is, when p and $q > 0$. If only one allele is present, the ratio is undefined.

We have now dealt with a single locus. If no epistatic interactions occur, the same will hold for the summated effects of many loci. Complications arise if there is any dominance

in the system. Consider again a single locus. Following L1 (1955), it is algebraically more convenient to assign the phenotypic value of 1 to the homozygous recessive condition (AA in our present notation) and the value of 0 to the heterozygote AA' and the homozygote A'A'. The mean of a generation under these circumstances will be equal to $p^2(0) + 2pq(0) + q^2(1) = q^2$. The variance will equal $p^2(0) + 2pq(0) + q^2 - (q^2)^2$. The covariance is equal to $q^1 - (q^2)^2$, and the correlation then will equal

$$\frac{q^1 - q^4}{\sqrt{(q^2 - q^4)(q^2 - q^4)}} = \frac{q^1 - q^4}{q^2 - q^4} = \frac{q}{1 + q}$$

Thus, in the situations where dominance exists, the expected value of the correlation is dependent upon gene frequencies. In the case of the different alleles being equally frequent ($p = q = .5$), the correlation would be expected to be .333. As the frequency of the recessive allele approaches 1, the expected correlation coefficient will approach .5. Similar considerations show that the expected correlation of siblings, given dominance and the other conditions assumed, will be .416 for $p = q = .5$, and approaches .5 as the frequency of recessive alleles increases.

A relatively large amount of research has been conducted on the correlations between parents and offspring and between siblings with respect to both anatomical and intellectual characteristics. The outcome is very often surprisingly close to the theoretically expected value of .5. Considerable caution must be urged, however, that this outcome not be accepted as demonstrating the existence of the restrictive conditions assumed in generating the model. Assortative mating, for example, is known to exist with respect to many of the traits in question. In some cases, the correlation of mates itself approaches the value of .5. In general this could be expected to raise the correlation coefficients.

Environmental factors, which have to this point been assumed to be negligible, may have a wide variety of effects. Perhaps a most common one would be the increase in variance, which would tend to reduce the correlation coefficient. Many other problems of a statistical nature are also encountered, such as those pertaining to the adequacy of the sampling procedures, or reliability of the measuring de-

vice. From the point of view of the behavioral scientist, the most interesting and relevant results have been those that pertain to measures of intelligence. Erlenmeyer-Kimling and Jarvik (1963) have recently reviewed the relevant literature. Twelve studies of parent-child resemblance on intelligence test scores provided correlation coefficients ranging from about .2 to about .8 with the median being at about .5. Thirty-five cases of correlation coefficients of siblings reared together gave values ranging from about .3 to about .75 with the median result, again, being at about .5. A difficulty of interpreting these results is that it is often not made clear if the correlation is between single offspring and single parent, to which case the preceding discussion pertains, or between sibship means and parent means, for which case there are different expectations.

Correlations among relatives may be related to the concepts of heritability. Actually, regression coefficients are more useful than correlation coefficients. The regression of offspring on one parent can be shown to estimate $\frac{1}{2} V_I/V_P$, or $\frac{1}{2}h^2$, where the symbol h^2 refers to heritability in the narrow sense described above. The regression of offspring on mid-parent estimates V_I/V_P and thus directly estimates h^2 . The intraclass correlation of full sibs is more complicated, yielding an estimate of $(\frac{1}{2}V_I + \frac{1}{4}V_D + V_F)/V_P$, where V_{EC} refers to that part of the environmental variance which is common to siblings. The study of sibs thus provides an "upper-limit" estimate of heritability.

Twin Research. The techniques of correlational or regression analysis are pertinent to the entire population, and then proper execution requires very careful representative sampling of the population under consideration. The next techniques to be discussed are applicable only to "special cases." One of the best known and most widely employed methods for this study of human genetics has been twin comparisons. There are actually several twin study methods which serve different research purposes. The basic twin method is the comparison of identical with fraternal twins. Identical twins (*monozygotic* or *MZ*) are individuals with identical genotypes, having arisen from the same fertilized egg. Fraternal twins (*dizygotic* or *DZ*), on the other hand, are no more alike genetically than are ordinary siblings. Any difference that appears

between members of an MZ twin pair must be attributed to differences in environment. Differences between members of DZ pairs, however, will reflect both environmental and genetic influence.

It is worth emphasizing that the primary datum in twin studies is a difference score. Now, if we may safely assume that environmental forces contribute no more to variability of the DZ than to the variability of the MZ twin pairs, a simple subtraction of the mean intrapair differences of a sample of MZ twins from the mean intrapair difference of DZ twin pairs should give an index of the genetic contribution to the differences between twins. More elegantly, the variances of the twin differences can be computed, and *F* ratios or intraclass correlations can be computed. The straightforward application of twin study results to the population at large is prevented by two features of the twin situation. The magnitude of the genetic effect is assessed by comparing differences between genetically identical individuals to the differences between genetically diverse individuals, the genetic diversity, however, is only that which can exist among progeny of the same parents. This will be much less variability than exists in the population as a whole. Similarly, the environmental forces whose impact is assessed by MZ pair differences are only those environmental differences that exist within a family. Again, this must certainly underestimate the range of environmental forces at work in the population.

Numerous criticisms have been leveled at the MZ-DZ comparison method. Perhaps the most serious of these is the likelihood that the range of environmental forces generating DZ intrapair differences is greater than that of the environmental forces contributing to MZ intrapair differences. If the environmental sources are not equal for the two types of twin pairs, we are left in a position of having two equations with two unknowns. Nevertheless, used properly, the twin method is useful in providing information about areas for future profitable research and also for setting limits. Furthermore, it should be noted that the objection concerning differences in environmental effects on MZ and DZ twin pairs is relevant only if these environmental differences are influential on the

trait under study. In some circumstances it may be possible to provide empirical data concerning the importance of differences in environmental effect between the two types of twins for a particular trait. Vandenberg (1965, 1966) has considered many of these criticisms in recent reviews.

The classical work involving comparison of MZ and DZ twin pairs typically employed more or less global measures of intelligence or personality traits (see McClearn, 1962, for review). Recently the trend has been toward the utilization of more specific tests, in keeping with new developments in psychometrics and test construction. A most important result of the application of specific factor tests is that the evidence for hereditary determinants differs from factor to factor. This is not only a valuable finding from the point of view of genetic interpretation, but it also offers the prospect of a model for experimental verification of the existence and identity of specific factors. Vandenberg (1966) presented data from two of his own large-scale twin studies and compared these results with those of two earlier investigators, Blewett (1954) and Thurstone et al (1955). Table 2 gives the values of the *F* ratio be-

Table 2 *F* Ratios between DZ and MZ within Pair Variance

Primary Mental Abilities Subtest	Michigan	Kentucky
Verbal	2.65 ^a	1.74 ^b
Space	1.77 ^b	3.51 ^a
Number	2.58 ^a	2.26 ^a
Reasoning	1.40	1.10
Word fluency	2.57 ^a	2.24 ^a
Memory	1.26	Not used

^a *p* < .01

^b *p* < .05

tween DZ and MZ within pair variances for six Primary Mental Ability subtests from the two Vandenberg studies, one conducted in Michigan, the other in Kentucky. The *F* ratios are significant, indicating a significant hereditary determinant, for verbal, space, number, and fluency. There is no evidence of hereditary determination for reasoning or for memory. An interesting suggestion in this connection has been made by Roberts (1967), who points out that a lack of evidence for genetic determination of a trait in a contemporary population may be inter-

interpreted as evidence for a high selective advantage of the trait in earlier evolutionary time, with natural selection having "used up" the additive genetic variance

The twin study methodology has also been brought to bear upon inheritance of normal personality traits. Gottesman (1963, 1965) has made extensive use of the Minnesota Multiphasic Personality Inventory and has found consistent evidence for hereditary influence in depression, psychopathic deviate, and social introversion. These and other researches, including many of his own, have recently been reviewed by Vandenberg (1967) in a summary of the accumulated evidence. Vandenberg concluded that there is clear evidence of a strong hereditary component for the personality dimension of extroversion-introversion, for emotionality, and for activity.

Another early use of MZ-DZ twin comparisons is in the study of the inheritance of psychosis. In dealing with quantitatively defined traits, such as presence or absence of schizophrenia, the results are usually considered in terms of *concordance*. The research design frequently involves screening of affected individuals resident in, or admitted to, an institution, determining those who have twins, and ascertaining whether the twin also has the condition. If so, the twin pair is scored as concordant; if not, they are discordant. Kallman (1953) reported that 86.2% of the MZ co-twins of schizophrenic patients were also or had been schizophrenic, whereas only 14.5% of the DZ co-twins of schizophrenics were also or had been schizophrenic. This has been a very active research area, and it cannot be adequately summarized here. A good recent review is provided by Gottesman and Shields (1966), who also present new data of their own. A particularly interesting feature of these data pertains to the hypothesis of biological heterogeneity in schizophrenia.

Rosenthal (1959) has suggested that the schizophrenia of concordant MZ twin pairs might differ from the schizophrenia of a member of a discordant MZ twin pair, with the latter more likely to be of environmental origin. Studies of other family members of concordant and discordant cases may then provide an approach to etiological distinctions. In analyzing some data obtained by

Slater, Rosenthal found that the condition was more severe in the case of concordant than discordant twins, and that there was a higher frequency of schizoid relatives in the families of concordant than in the families of discordant twins. The results of Gottesman and Shields (1966) confirmed the findings concerning a differential in severity. Defining severe schizophrenia as requiring more than one year of hospitalization, and mild as requiring less, MZ concordance for the severe schizophrenics was 67% compared with a concordance rate of 20% for mild MZ schizophrenics. These authors point out that if the predisposition to schizophrenia is a polygenically determined characteristic, possession of a number of alleles making for increased susceptibility to schizophrenia would probably at the same time make for greater severity and for an increased likelihood of a co-twin developing similar symptoms.

Another variant of the twin study method involves the comparison of MZ twins reared together and MZ twins reared apart. It should be noted that in this paradigm, there is no genetic variance. Such comparisons therefore provide no evidence concerning the heritability of a trait, although they are useful in assessing the impact of various environmental factors and are useful as adjuncts in a MZ-DZ comparison. The classical work of this type is that of Newman et al. (1937). More recent examples are provided by Shields (1962) and Burt (1966). In the intelligence measure employed by Shields (1962) the intraclass correlation for MZ twins reared apart was .77 and for MZ twins reared together was .76. By comparison, the value for DZ twins reared together was .51. On the basis of these values, the environmental differences of upbringing appear to have had but little influence on the intelligence of the MZ twins. In an extensive study Burt (1966) included observations on a variety of biological relationships among twins reared together and apart. The correlations for MZ twins reared together and MZ twins reared apart was .92 and .87, respectively. DZ twins reared together gave a value of .53, as did siblings reared together. The intraclass correlations of siblings reared apart was .44 and for unrelated children reared together was .27. These results are clearly consistent with a genetic interpretation.

The co-twin control procedure is essentially a controlled variant of the method of comparing MZ twins reared apart to MZ twins reared together. Instead of a prolonged environmental difference persisting over a long developmental period, a specific and well controlled environment, usually special training, is given to one of an MZ twin pair, with the other being untreated for control comparison.

A method complementary to twin studies involves the observation of adopted children. The basic logic is that any resemblance between an adopted child and his adopted parent will be of environmental origin. Comparisons of correlations of this kind with correlations of children living with their biological parents should then provide some estimate of the relative influence of genetic and environmental factors on the trait in question. Honzik (1957) presented data on correlations between child's IQ and education of mother and of father and compared these values to those obtained by Skodak and Skeels (1949) in a study of the relationship of adopted child's IQ to true mother's education and also to foster mother's education. In brief, the finding was that the relationship of adopted child's IQ to true parent education followed the same course over time as that of a child reared by its own parent, with the correlation leveling off at about .35. The relationship of the adopted child's IQ to the foster mother's education never exceeded a value of .10, and in the case of the relationship of the adopted child's IQ to foster father's educational level, the correlation never exceeded .05.

Other variants of studies of adopted children have involved comparison of children's IQ scores before and after placement, or the comparison of groups placed in homes of different socioeconomic level. These approaches provide valuable information concerning the influence of environmental factors, but they are not really relevant to genetic study.

Other Methods Although the described methods have been those most widely employed in human behavioral genetics, other approaches are possible. Cattell (1953), for example, has proposed a multiple variance analysis system that would estimate genetic parameters from a series of equations relating

observed variance of particular family groupings to theoretical environmental and genetic components and their interactions. In another paper, Cattell (1963) reviewed some research that had been conducted using the multiple variance analysis system on the inheritance of personality. The evidence currently indicates that there is high heritability of the cyclothyme-schizothyme, excitable-phlegmatic, and superego strength factors. Environment appears to be the principal determinant of the dimensions of *tender* versus *tough minded* and *fatigability* versus *will responsiveness*, however.

A novel approach to the study of hereditary determination of components of intelligence was provided by Schull and Neel (1965), who assessed the effects of inbreeding in a Japanese population upon performance on a version of the Wechsler Intelligence Scale for Children. Various degrees of inbreeding were investigated, including offspring of second cousins, of first cousins, and of first cousins once removed. As we shall see later in the discussion of animal research, the effect of inbreeding is to increase homozygosity. The offspring of consanguineous matings will tend to be homozygous at more loci than will members of the general population. Homozygosity for the recessive alleles at many loci appears to be detrimental. It was therefore of great interest to examine the effect of this relatively modest degree of inbreeding upon intelligence. Using the mean of a control, "outbred," group of children as a reference point, depression of the various WISC subtest scores was consistently found for the children of the consanguineous matings.

Animal Research

In animal research it is, of course, possible to control matings of the experimental subjects, and thus several methods for the study of behavioral inheritance are possible which cannot be utilized in studies on man. One of the most widely used of these has been the comparison of inbred strains.

Inbred Strains Inbreeding, or the mating of related individuals, leads to an increase in homozygosity of the offspring. This is basically due to the fact that relatives are more likely to share alleles by virtue of their common ancestry. In animal research, close

inbreeding, usually brother by sister, is employed. If this procedure is repeated over generations, with each generation derived from the mating of a single sibling pair, the result will theoretically be an asymptotic approach to a condition of homozygosity at all loci. This state of "purity" for practical purposes can be regarded as being attained after 20 consecutive sib-mated generations. Several factors prevent the attainment of this ideal (see McClearn, 1967), but as an approximation and a working model, strains bred in this fashion may be regarded as genetically homogeneous. A number of inbred strains of mice exist. In the main, these strains were developed for cancer research, but many also differ widely with respect to various behavior patterns.

The logic of strain comparisons is essentially as follows. The likelihood of any two separately developed inbred strains coming to be homozygous for the same alleles at all then (perhaps 100,000) loci is vanishingly small. Therefore, if two or more strains are reared and maintained under the same environmental conditions, and if differences in behavior are manifested between any of them, the difference must be attributed to genotype differences. The discovery of the strain difference in behavior therefore serves as a demonstration that there is an important genetic component in the behavior. Such demonstrations have now become commonplace, with differences in activity (Thompson, 1953; McClearn, 1959; Buell, 1962; DeFries, 1964), learning (Lindzey and Winston, 1962; Carian et al., 1964), hoarding (Manosevitz and Lindzey, 1967), sexual behavior (McGill, 1962), alcohol preference (McClearn and Rodgers, 1959; Fuller, 1964), aggressiveness (Scott, 1942; Ginsburg and Allee, 1942), dominance (Lindzey et al., 1961), and others.

Such demonstrations of genetic influence on behavior patterns provide little evidence concerning the nature of the genetic system, and they should be regarded primarily as entering wedges for subsequent research oriented toward analysis of the quantitative aspects of the genetic system or the physiological mechanisms through which the genes are expressed. Examples of the latter type of research will be discussed later. The assessment of quantitative parameters of the genetic system utilizing inbred strains depends

upon the fact that the inbred strains themselves are genetically uniform, as are the first generation hybrids between them, but that subsequent generations are genetically heterogeneous. Consider, for example, one strain that is homozygous $AABBC'C'$ and another that has the genotype $A'A'B'B'C'C'$. If these two strains are crossed, each can make only one kind of gamete. The first-named strain can produce only ABC' gametes, and the second-named strain can produce only $A'B'C'$ gametes. When these gametes unite the offspring will be $AA'BB'C'C'$. Thus the offspring will be heterozygous at all loci at which the parent strains differ but will still be homozygous at those loci at which the parent strains were homozygous in like state. Although heterozygous at many loci, all individuals within an F_1 generation will be identical genotypically. When matings are made among individuals from within this F_1 generation, segregation occurs and the F_2 generation will be genetically heterogeneous. Variability within the inbred parent strains or then derived F_1 must be attributed to environmental factors, since there is no genetic variability within these groups. Phenotypic variability of the F_1 group, however, will be due to both genetic and environmental factors. These relationships permit the estimation of the degree of genetic determination of a trait. For example, using closely related inbred mouse strains as parent strains, two different investigations (Fuller and Thompson, 1960; McClearn, 1961) provided estimates that the degree of genetic determination for open field activity was about 6. That is, about 60% of the variance of the F_2 generation was due to genetic activity differences.

Selective Breeding Another research methodology available to the animal researcher that is not possible for human research is selective breeding. In this procedure, a sample of animals is measured with respect to some trait, and the ones showing an extreme manifestation of the trait are chosen to be the parents of the next generation, the extreme individuals of this offspring generation are again chosen to become parents of the succeeding generation, and so on. Providing that there is a genetic contribution to the variance of a trait in the initial population, this procedure will result in a systematic in-

crease in the mean of the trait over the succeeding generations. The amount by which the mean will shift is dependent upon the relationship $R = h^2S$ where R refers to selection response, S refers to selection differential, and h^2 refers to heritability in the narrow sense. The selection differential is the difference between the mean of those selected to be parents of the next generation and the mean for the entire generation of which the parents were members. The selection response is the difference between the mean of the parent's generation and the mean of the offspring generation. Thus, when heritability is high, selection response will be rapid. When heritability is low, selection response will be slow. A successful selective breeding study thus demonstrates that the trait in question had a significant additive genetic component.

A number of selective breeding studies with rats have followed the pioneering effort of Tolman (1924). Probably the best known is Tryon's work (1940) in which one strain of rats was selected for superior performance in a 17-unit multiple T maze and another strain, from the same foundation population, was selected for poor performance in the same maze. This procedure of selecting bidirectionally is necessary because of the shifts in mean within any single strain that can occur because of environmental fluctuations. The critical information therefore becomes that of the difference between the two lines selected in opposite directions.

A study contemporaneous with Tryon's was that of Heron (1941), who also was successful in selectively breeding for maze dullness and maze brightness in rats. Yet another successful maze learning selection study with rats employed the Hebb-Williams maze (Thompson, 1954), and more recently, successful selection for conditioned avoidance responses has been described (Bignami, 1964). Selection for high and low emotionality, as measured by defecation in a brightly illuminated open field, was undertaken by Hall (1938). This work was replicated by Broadhurst (1958). Rundquist (1933) selectively bred for high and low activity in rats. With mice, there has been successful selection for aggressiveness (Lagerspetz, 1961), alcohol preference (McClearn, unpublished), open-field activity (DeFries and Hegmann,

in press), and audiogenic seizure susceptibility (Frings and Frings, 1953). Sex drive (Wood-Gush, 1960) and aggressiveness (Guhl et al., 1960) have been successfully bred for in chickens. In insects, with a short generation interval, selection studies may be carried out over many generations in a relatively short period of time. Hirsch and Boudreau (1958) selected for phototaxis in *Drosophila*. Subsequently, Erlenmeyer-Kimling et al. (1962) selectively bred for high and low manifestation of geotaxis in *Drosophila*. Manning (1961) has selectively bred for mating speed in *Drosophila*, and has provided an example of the technique of estimating heritability from the selection response, since $R = h^2S$, $h^2 = R/S$. In Manning's case, "realized" heritability calculated in this fashion was 30.

After a behavioral difference has been established between two inbred strains, or after a selective breeding program has generated strains of animals highly different on some behavioral trait, these animals become valuable research material for testing hypotheses about correlated traits at the behavioral level of analysis, or about physiological mechanisms underlying the traits. Several examples of the utility of selected animals in exploring related behavioral variables may be cited. Singh (1959) sought to determine the generality of the "emotional" response of the rats selected by Broadhurst for "reactivity" and "nonreactivity" as measured by defecation in the open field situation. Rats of the reactive strain were found to acquire a conditioned emotional response more rapidly than did animals of the nonreactive strain. Insights into the nature of the performance difference between the Tryon "maze bright" and "maze dull" rats were provided by Kiechevsky (1933) who found that bright rats responded more in terms of spatial stimuli, and the dull rats responded more in terms of visual stimuli. Searle's (1949) work implicated motivational and emotional factors in determining the performance differences of these two strains. In descendants of the Tryon strains, McCaugh et al. (1962) have shown that the strain differences are most pronounced with very short intertrial intervals. As the distribution of practice was increased the differential between the strains diminished, and, at a

24-hour intertrial interval, the difference vanished entirely. These results suggest a difference in the consolidation mechanism in the two groups of animals. Examples of the use of inbred and selectively bred animals for the study of physiological mechanisms will be given later.

THE CHEMISTRY OF GENETICS

During the last 15 years there have been enormous advances in the understanding of the biochemical and physiological mechanisms through which the effects of genes are manifested. Fundamental to these developments has been the clarification of the chemical nature of the gene itself. The fundamental component of hereditary material is deoxyribonucleic acid (DNA). A DNA molecule has a double helical structure as shown in the schematic representation in Fig. 9. The two strands are composed of sequences of phosphate and deoxyribose sugar groups and they are held a fixed distance apart by pairs of bases on the interior of the helix. The stereochemical limitations of this molecular structure are such that the four bases involved (adenine, thymine, guanine, cytosine) can only pair in two combinations. Adenine always pairs with thymine, and guanine always pairs with cytosine. The doubled nature of the DNA molecule and the restrictions on base pairing make possible one of the essential features of hereditary material, that of self-duplication. Obviously, the genetic material must be duplicated many times over in the process of development from a single fertilized cell into a complex, multicellular organism. Evidently, in the process of cell division, the helices of the DNA molecule unwind, with the base pairs separating and one of each pair going with each strand. The raw materials from which the DNA molecule is formed appear to be plentiful in the nucleus of the cell. These raw materials occur in the form of nucleotides, consisting of one of the four bases, a deoxyribose sugar, and a phosphate. The bases of these nucleotides come to pair with the exposed bases of the unwound strands, and in this way complementary strands are formed against the originals. Eventually two DNA molecules exist where there had been but one.

The chromosomes containing DNA are

Fig. 9 Schematic representation of a DNA double helix

located in the nucleus of the cell, yet much of the biochemical work of the cells takes place in the cytoplasm. It is therefore necessary that the "information" that is coded in the DNA molecule be transmitted to the cytoplasm. This is accomplished in two steps. The first step is a transcription of the information from the DNA molecule onto a single-stranded ribonucleic acid (RNA) molecule. In reactions similar to those involved in the duplication of DNA strands, RNA can be formed in a specified sequence against one of the DNA strands. RNA is composed of a ribose sugar, phosphate, and the same bases

found in DNA, except that in RNA uracil substitutes for thymine

This so-called messenger RNA molecule then may enter the cytoplasm where it becomes involved in protein synthesis. The genetic "information" has been shown to be coded by triplet sequences of bases, with each succeeding triplet specifying an amino acid, for example, three uracils in a row (UUU) specifies phenylalanine, UAU specifies tyrosine. There are 64 possible triplet combinations of bases, yet there are only 20 amino acids used in the formation of animal protein. This means that there is some "degeneracy" in the code, with more than one triplet pair able to specify a particular amino acid. For example, UUC, as well as UUU, specifies phenylalanine. The sequence of base triplets therefore determines the sequence of amino acids which constitute a protein molecule. Enzymes are proteins that act as catalysts and are vital to the operation of the organism. Indeed, pressure and temperature conditions within living tissue are such that the essential reactions could not take place in the absence of these organic catalysts. These reactions ultimately give rise to the structure of the organs of which the body is constituted and direct their function. It is, furthermore, worth noting that genetic transcription and RNA synthesis are themselves processes which are catalyzed by enzymes.

Up until the present time, few of the data of behavioral genetics have been directly related to steps between the DNA of the gene and the formation of enzymes. Beginning at this point, however, there is an accumulating body of evidence relating genetically determined enzyme differences to behavioral consequences. The classical example is phenylketonuria. In 1934 Folling described a biochemical defect in a particular type of mental retardation now known as phenylketonuria, phenylpyruvic oligophrenia, phenylpyruvic idiocy, or Folling's disease. Shortly thereafter this condition was shown to be inherited in a simple Mendelian recessive manner (Jervis, 1937). The clinical picture of phenylketonuria involves a generally reduced stature, light pigmentation, microcephaly, hand posturing, rhythmic rocking back and forward, temper tantrums, and, frequently, abnormal EEG patterns (Hsia, 1967). The distribution of intelligence scores

in the institutionalized and untreated cases of phenylketonuria is markedly positively skewed, with approximately 50% of the cases falling below an IQ of 20 and with over 90% of the cases falling below an IQ of 50 (Jervis, 1954). Some untreated individuals have been found to have intelligence within the normal range, however.

The biochemical difficulty arises from an inability of the affected individuals to convert phenylalanine, an essential amino acid, into tyrosine. This inability is due to a deficiency of the liver enzyme phenylalanine hydroxylase. In fact, it has been shown (Mitoma et al, 1957, Wallace et al, 1957) that the enzyme has two fractions, one of which is labile and found only in the liver, whereas the other is stable and found in several tissues. Phenylketonuric patients are deficient with respect to the labile fraction only. Biochemical inadequacy at this single step has widespread consequences, as described in recent reviews by Hsia (1967) and Menkes (1967). Figure 10 shows some of the relationships of the involved metabolites. The inability to convert phenylalanine to tyrosine results in an accumulation of phenylalanine, which is converted to phenylacetylglutamine. The presence of an excessive amount of phenylalanine inhibits the conversion of tryptophan to 5-hydroxytryptamine with a consequent reduction in the blood level of the last-named substance. Excessive phenylalanine also inhibits conversion of tyrosine to melanin, thus accounting for the reduced pigmentation of affected individuals.

An understanding of the metabolic lesion naturally suggests therapies. Since it is not yet possible to supply intracellular enzymes, the therapeutic approach has been to reduce the dietary intake of phenylalanine. This was first done by Bickel et al (1954), and a number of reports are now available on the effectiveness of the treatment. It seems quite apparent that a normalcy of the chemical milieu can be maintained by the dietary therapy. It is also generally agreed that there is an improvement in intellectual functioning, although disagreement persists as to its extent. One of the principal problems in assessing the extent of improvement is in the selection of a control group. Properly, such a control comparison group should be all of

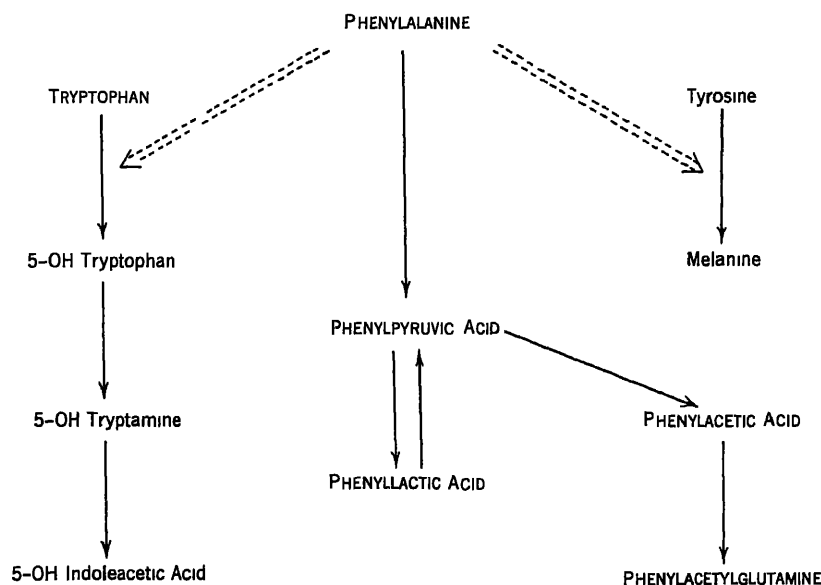

Fig 10 Metabolic pathways in phenylketonuria

the untreated individuals with the biochemical lesion. A number of these individuals, however, are of normal intellectual competence, and are therefore not available in institutional settings. Hsia (1967) has summarized several studies, including his own, on the IQ level attained by patients who were given therapy beginning at different ages. There is a general decline in attained IQ level as the age of beginning of treatment increases. It is furthermore noteworthy that the highest IQ levels attained were around 100. Sutherland et al., (1967) has reported a somewhat more favorable outcome in a study of the intelligence of 7 patients for whom treatment was begun prior to 11 weeks of age. The mean IQ of these 7 was 110, as compared to an IQ of 106 for 10 of their unaffected siblings. However, 5 siblings who were affected and either untreated or treated beginning at a late age had a mean IQ of 68. The mean IQ of 5 treated patients, whose treatment began from 9 to 12 months of age, was 78. The necessity of early treatment is indicated by these data, and it is further emphasized by the results of Baumeister (1967), who studied the effects of dietary treatment in 162 phenylketonuric patients. The results are shown in Fig 11.

Many states now include the testing of newborn children for phenylketonuria. The

frequency of the condition appears to be about 1 in 10,000 live births.

For purposes of genetic counselling, as well as for research purposes, an ability to identify heterozygotes is important. Hsia et al. (1956) provided a method for detecting heterozygotes for phenylketonuria by means of a phenylalanine tolerance test. After a given dose of L-phenylalanine is administered orally, blood levels of phenylalanine are found to be higher in heterozygotes than in normal controls. This finding illustrates the fact that the mode of gene action is not always the same at all levels of analysis. At the level of mental defect, phenylketonuria appears to be a "good" recessive with no manifestation in the heterozygote. At the level of biochemical functioning, however, the heterozygotes are seen to be affected to some extent.

Numerous other conditions involving abnormal metabolism of an amino acid have been described, and, with the investigation of phenylketonuria serving as a model, research oriented toward detailed description of the metabolic consequences, and possible rational therapy, is proceeding rapidly. (See Nyhan, 1963, for a review of some of these conditions.)

Other types of metabolic disturbance have also been identified in genetically determined

Fig 11 Relationship between age at beginning of treatment and attained IQ in phenylketonuric patients (Data from Blumeister, 1967)

conditions involving mental retardation. Two types of amaurotic idiocy, for example, have been described which involve accumulation of abnormal quantities of lipid substances in the nervous system. The first of these conditions, Tay-Sachs disease, or infantile amaurotic idiocy, involves mental deterioration which proceeds rapidly to complete idiocy. The onset of symptoms is typically at 5 or 6 months, and the average age of death of these patients is about 18 months. Juvenile amaurotic idiocy, which is also referred to as Spielmeyer-Vogt disease, has an onset at about 6 years of age with progressive degeneration extending over a period of 5 to 10 years, during which intelligence level falls from normal to profound idiocy. Both of these conditions are inherited in a recessive manner. The reader interested in discussions of these and other similar conditions is referred to Penrose (1963).

Although this chapter is particularly oriented toward evidence derived from studies on man, it is appropriate to mention briefly some of the studies with experimental animals that have identified anatomical, bio-

chemical, or physiological intermediates between genes and behavior.

A systematic attempt to describe relationships between learning ability, brain biochemistry, and brain morphology has been made by Rosenzweig and co-workers (1960). The starting point of their research was the exploration of differences in brain acetylcholinesterase between the S_1 and S_2 rat strains, which were descendants of Tison's maze bright and maze dull strains, respectively. Selective breeding has also been employed to alter the enzyme activity with subsequent examination of behavioral differences. Thus four lines have been selectively bred for high and low brain acetylcholinesterase activity, and two lines have been selectively bred for high and low acetylcholine concentration in the brain. The conclusion of these studies has been that the critical factor is the ratio of the substrate acetylcholine to acetylcholinesterase.

Another example of research into mechanisms of gene action is the work of Ginsburg (1967). Ginsburg found audiogenic seizure susceptibility in mice was associated with the activity of the enzyme nucleotide triphospha-

tase in the granular cell layer of the dentate fascia of the hippocampus. Other research on causal dynamics of audiogenic seizure susceptibility (Schlesinger et al., 1964) has shown that deficiency of serotonin and norepinephrine in the brain may be responsible for the differences in seizure susceptibility in different strains of mice.

DEVELOPMENTAL GENETICS

It is most important to appreciate that the influence of genes is not manifested only at conception or at birth or at any other single time in the individual's life history. Developmental processes are subject to continuing genetic influence, and different genes are effective at different times. Several examples of Mendelian inheritance in man may illustrate this point. The timing of gene action, for example, is shown by the late age of onset of Huntington's chorea, to which reference has already been made. The genes responsible for determining blood groups, on the other hand, appear to have their effect early in the development of the fetus, and the phenotype remains unaltered throughout life. Yet another characteristic, hemoglobin type, changes very dramatically early in life but remains stabilized thereafter. In a more complex case, presumably subject to the influence of a number of loci, Vandenberg and Falkner (1965) performed a twin study on human growth and found evidence for genetic control of growth rate and of deceleration of growth rate, but not for length at birth.

Other examples may be drawn from research with animals. Hiubant (1964) investigated the effects on longevity of different alleles at a single locus in the inbred mouse strain designated C57BL/6. This strain is usually homozygous for an allele (*a*) that renders the coat color nonagouti. By various mating procedures it is possible to substitute other alleles at this locus, and it was found that the substitution of either *A* or *a⁺* resulted in a significant decrease in life span of animals.

The genetic control of a developmental anomaly in mice is illustrated by the condition known as *Kreisler*. *Kreisler* is inherited as a recessive, and the homozygous recessive animals at 10 to 14 days of age begin crawling in circles, become rigid when placed on the

back, and are subject to head shaking and tossing and running in small circles. Some survive and reach sexual maturity. The affected individuals have one or two liquid-filled cysts under the pons which compress the adjacent brain structures. This results in a gross deformation of the telencephalon in general. The condition is identifiable in embryos at about 9 days of age, due to the fact that the otic pit is situated at some distance from the neural folds in the homozygous recessive animals. The embryological interactions in the development of *Kreisler* animals is described by Deol (1964).

A demonstration of presumably polygenic influence on developmental processes in rats is provided by Stone and Barker (1940), who selectively bred for early and late puberty. In the sixth generation the mean age of onset of puberty for the early and late strains, respectively, were, for males, 47.6 and 61.2 days and for females, 43.0 and 56.9 days.

Fraser and co-workers have demonstrated a genetic difference in susceptibility to the teratogenic effect of injected cortisone during embryological development. Fraser et al. (1954) showed that the administration of cortisone to pregnant *A* strain mice resulted in cleft palates in 100% of the offspring. Similar treatment to C57 mice resulted in the cleft palate abnormality only in 17% of the offspring. In later research they (Walker and Fraser, 1957) traced the embryology of the palate in the two strains under the experimental and control conditions. They concluded that the strain difference in susceptibility to the teratogenic action of cortisone is attributable, at least in part, to the normally earlier closing of the palate in the C57 embryos under control conditions.

Models of Control of Gene Action

The preceding examples, of only marginal behavioral interest, should serve to document the fact that genes exert influence over developmental processes. Important progress in understanding the means by which genes may be "turned on" or "turned off" has been made recently. The *operon* model of gene action (Jacob and Monod, 1961) has been particularly valuable. Although the basic data were obtained from research with microorganisms, it now seems a reasonable working hypothe-

sis that similar mechanisms may occur in higher organisms (Uisprung, 1965)

The operon model postulates two different types of genes, regulator genes and structural genes. The discussion up until this time has been concerned with what under this model would be described as structural genes, whose function is to produce messenger RNA, which will in turn eventually result in enzyme formation. A structural gene has an operator adjacent to it. The operator is a segment of DNA which is apparently the critical starting point for the molecular transcription of RNA and DNA. A regulator gene, which may or may not be physically adjacent to the operator or the structural gene, produces a repressor substance that attaches to the operator and thus inhibits transcription of RNA molecules from that particular structural gene.

These features of the model are represented in the top part of Fig. 12. An "inducer" may enter the system by, for example, diffusion from adjacent cells or from the external environment. This inducer combines with the repressor, and the compound is now unable to occupy the strategic site on the operator. RNA transcription and the consequent enzyme production can then proceed. The gene has been "turned on." This situation is represented in the bottom part of Fig. 12. If one

of the metabolic products that results from the reactions initiated by the enzyme is the inducer or a similar molecule, the effect is to keep the gene locked on. A similar mechanism can turn off or lock off a gene that is initially on. Although this mechanism has not been demonstrated in mammalian systems, it provides a useful conceptual framework for viewing processes of growth and differentiation. By this mechanism or similar mechanisms, genes may be turned on or off at different times and in different parts of the developing organism. That systematic, genetically controlled differences in enzyme activity over time and in different organ systems do occur in mammals is shown by the research of Paigen (1961). Animals of the C3H strain have much lower activity of the enzyme β -glucuronidase than animals of the DBA/2 strain. The relative specific activity of the various organs of the C3H animals as compared with DBA animals is shown as a function of age in Fig. 13. The differences of the age function for the different organs and the strain differences are obvious.

Chromosome Puffs

Another type of evidence that relates developmental processes to differential gene ac-

Fig. 12 The operon model

tivity is provided by research on chromosome puffing (Beerman, 1963). In some tissues of the larvae of certain insects, giant chromosomes exist which are visible under the ordinary light microscope. Because of their size these chromosomes have been intensively studied, and one phenomenon that has been described is the "puffing" of different regions of the chromosomes. Puffing is reversible; the puffs show signs of intensive RNA production, only a small percentage of the chromosomal loci puff in any given cell, and the pattern is different for different tissues and within any one tissue during different developmental phases. These features strongly suggest that the chromosome puff is a physical manifestation of the activity of one or a few gene loci. In *Chironomus*, further research has provided evidence that hormones may be effective in control of gene activity. The hormone ecdysone is normally found in the larvae during the molt. When ecdysone is administered to a larva not yet old enough for spontaneous molting, a series of events is initiated which is typical in the untreated animal at the normal molting time. Thirty minutes after the injection, a puff appears on one chromosome and this puff persists until the molt is complete. Thirty minutes after the first puff appears, there appears on a different chromosome another puff which lasts for two days and then recedes.

Quantitative Models

The operon model and the evidence of sequential gene action in chromosome puffs, derived from research on microorganisms and insects, are useful concepts for guiding theory and research in the genetics of mammalian development. Nevertheless, in complex systems involving many loci, theories that can account for developmental phenomena in terms of statistical descriptions of the aggregate actions of the separate loci and the complexities of interactions among the loci would be useful. Unfortunately, completely satisfactory theories of this type have not yet been developed. Waddington (1962) has pointed out the need for formulations that bridge the gap between the rapidly increasing knowledge of molecular genetics and the phenomena of metazoan embryology. It appears likely that this type of theory will be most pertinent to

Fig 13 Relative specific enzyme activities in various organs of mice as a function of age

many of the problems of developmental psychology.

Waddington (1962) has provided valuable contributions to this theoretical development. The basic elements of developmental theory, he maintains, are stabilized or buffered pathways of change, which he terms "creodes," from Greek roots meaning, essentially, necessary path. A system with a multiplicity of genetic determinants can be described as a point in n -dimensional space, and, geometrically, the creode may be envisioned as a trajectory of this point through the n -space, toward some specified endpoint. The buffering characteristics of a creode are such that, when deviations from the trajectory occur as the result of some disturbance, there is a tendency for the system not simply to adopt a new path to the old endpoint, but to return to the original pathway leading toward the endpoint (Waddington, 1957). Tanner (1963) has provided empirical data on this "catch-up" process in the growth curves of children whose growth is disturbed by illness.

Such a system must obviously involve feedback loops, probably of great variety and complexity. Waddington (1962) describes various contributions toward the development of mathematical formulations of control systems in developmental genetics; the details

Fig 14 Waddington's "epigenetic landscape"

of which cannot be reviewed here. A three-dimensional physical analogy serves to convey some of the essential points of creodic functioning, however. Figure 14 shows Waddington's "epigenetic landscape," which he warns is only suggestive and not to be interpreted in any literal sense. Briefly, the contour of the landscape is determined by genotype, and the position of the ball represents the value of the developing phenotype. In the developmental process, represented by the ball rolling forward, environmental forces may act laterally upon the ball and displace it from its path. At crucial moments such a displacement can shift the system into a new channel of development. An important property of creodes is represented in this schema by the cross section of a valley in the epigenetic landscape. A wide valley floor with gradually sloping sides represents a developmental pathway that is not well buffered, and permits environmental forces to displace the phenotype considerably. A narrow floor with steep walls, on the other hand, represents a highly buffered or canalized pathway.

Both the genetic control of growth trajectories and the relative degree of canaliza-

tion of these trajectories are shown in research on mice by Roberts (1961). Animals of six different genetic groups were weighed at regular intervals through their entire life span. The RCL and NF stocks had been selectively bred for high six-week weight, the MS and NS were selected for low six-week weight, the $M \times R$ was the F_1 generation of a cross between MS and RCL, and the NC was an unselected control stock. The mean growth curves of the males of the different stocks are shown in Fig 15. Not only are there clear differences in highest body weight attained but, in the large strains, there are obvious declines which occur at different ages. Clear strain differences are apparent also in longevity, indicated in the figure by the point of termination of the lines. In Fig 16 the growth curves of individual animals are shown. These results show differences in canalization of the growth process in the various strains.

Again, it should be emphasized that the epigenetic landscape is offered as a simplified model only; it may serve, however, to indicate the sort of theoretical formulation that may be required to account for the inter-

Fig 15 Cumulative growth curves of male mice for each stock

actions of genotype and environment in behavioral development

Undoubtedly, as research progresses, translations may be made from one theoretical level to another. Tanner (1963), for example, in discussing the cases of "catch-up" growth in children, proceeds from control system notions to molecular speculations. The key elements necessary in an automatic closed-loop control system are an output signal, a command signal, and the error signal that results from a discrepancy between these two (Wilkins, 1966). The command signal in this case is the size the organism "ought" to be if the developmental trajectory had not been disturbed. The output signal is the size actually attained. Tanner proposes that the output signal is the concentration of some substance that is an inevitable consequence of protein synthesis. Thus the mass of the body would be directly proportional to the concentration of this substance, which he calls "inhibitor." The command signal may be the number of molecules of some other substance that has a receptive site for "in-

hibitor" and which increases directly with elapsed time. The error signal would be the number of unoccupied sites, and would result in the release of a growth-promoting substance. When, as a consequence of accelerated growth, the number of inhibitor molecules equals the number of receptive sites, no more growth-promoting substance would be released until the passage of time provided yet more receptive sites. Tanner speculates further that the rate of accumulation of receptive sites, and the rate of change of that rate, may be an inherited characteristic.

Developmental Genetics and Behavior

In a very real sense it is the case that any demonstrated genetic control over an adult characteristic is, at the same time, an implication of genetic control over the developmental processes that culminate in that characteristic. Research aimed explicitly at studying the genetic control of behavioral development unfortunately has been rare, particularly with respect to man. The re-

Fig 16 Individual growth curves of male mice, showing differences in growth pattern between stocks (Five NS males lived longer than shown, but some of their weights inadvertently were not recorded)

Fig 16 (Cont'd)

search that has been conducted, however, has demonstrated well the advantages of the developmental genetic approach to behavioral processes, and it appears to be a safe prediction that work in this area will increase rapidly in the immediate future.

Human Research That genetic control of developmental processes persists over the entire life span has been shown by Jarvik and her colleagues (1957, 1962), who have studied intellectual functions in aged twins. Patterning or sequence of developmental events, rather than simple timing, was emphasized by Sontag and Gan (1956/57), who examined sibships for developmental patterns of a number of physical and behavioral traits. Certain patterns of development of body size, motor coordination, and other traits were found to be characteristic of families.

The data summarized by Honzik (1957) are particularly suggestive of developmental genetic processes that determine the increasing degree of resemblance of offspring and parent on intellectual measures during the first years of life. Problems of test inadequacy in the earlier years may account for some of this developmental trend, but it may also be that the increasing resemblance is a reflection of the "switching on" of more and more genes that play a role in intellectual functioning.

Animal Research The research on animals has fallen into two general categories: descriptive studies of different developmental sequences in groups of different genotype, and experiments concerned with assessing the impact of environmental manipulation upon animals of different genotypes. Of the descriptive studies, several have been concerned with audiogenic seizures in mice. Schlesinger et al (1964), for example, have described a very sharp peak at 21 days of age in seizure-susceptibility to audiogenic stimulation of a "high susceptibility" strain of mice. It is particularly interesting that only at that age do animals of this strain differ in brain serotonin and norepinephrine from animals of the "low susceptibility" strains. Fuller and Sjuisen (1967) have reported many different patterns of convulsive risk and of death risk in 11 different inbred strains exposed to audiogenic stimulation.

Thiessen (1965) investigated behavioral aspects of the "wabblers" lethal condition in

mice. Homozygous recessive animals display hind limb incoordination and paralysis, with accompanying myelin degeneration, beginning at about 14 days of age. Developmental changes are under way prior to the appearance of these most obvious symptoms, however. For example, activity in an open field arena is affected as early as 10 days of age.

In studies of learning of mice in a water maze, Meier and Foshee (1963) and Meier (1964) have shown that strains not only differ in learning performance at any given age, but that there are, as well, widely different developmental functions. A strain by age interaction was also shown by McGaugh and Cole (1965) in rats. Both S_1 and S_2 strains showed improved performance under distributed practice as compared to massed practice when tested at 142 to 164 days of age. For the S_2 strain, this improvement was also found at 29 to 33 days of age, but practice distribution had no effect upon S_2 animals at that age.

Yet another example may be taken from alcohol preference in mice. Kakihana and McCleain (1963) described a marked and abrupt decrease in alcohol preference of one strain of mice, at about 9 weeks of age, but found no corresponding function in the other strains investigated.

In experiments that involve the manipulation of environmental circumstances of different genetic groups during development, evidence of genetic influence on the developmental process is essentially an interaction of genotype and treatment. The duration of application of the experimental procedure in these studies has ranged from very brief to quite long term. An example of genetic differences in response to long-term environmental conditions is provided by the research of Freedman (1958) in which dogs of four breeds (Shetland, Basenji, wheaten, fox terrier, and beagle) were reared under "indulgent" or "disciplinary" regimes. Disciplined pups were restrained and taught to obey commands. Indulged pups were encouraged to undertake all manner of activity and were never punished. These conditions persisted from the third to the seventh week of life, at which time each dog was tested in the following manner. When the dog ate from a food bowl in the center of the room, he was punished by a swat and shout from

the experimenter. After three minutes the experimenter left the room and the time until the animal returned to eating was recorded. Mode of rearing was found to have a large effect on beagles and terriers, with disciplined animals returning to eat much sooner than the indulged animals. For the other breeds, mode of rearing had no effect. The Basenjis of both groups ate quickly, suggesting that they were relatively unaffected by the treatment. The Shetlands of both groups, on the other hand, were so affected by the punishment in the test situation that they avoided the food entirely.

Another experiment on the effects of long-term rearing conditions is that of Dixon and DeFries (in press). Mice of two inbred strains (BALB/c and C57BL/6) were reared under high illumination or low illumination conditions from birth until 40 days of age, at which time they were tested for activity in an open field apparatus. BALB/c mice reared under high illumination had higher activity and lower defecation scores than those reared under low illumination, whereas C57BL/6 mice were not affected by rearing illumination.

Different sublines of these strains were studied by Ressler (1963) in an experiment on the effects of foster rearing on panel press manipulation, and panel press for illumination. BALB/c mice were more manipulatory than C57BL/10 mice whether they were reared by BALB/c parents or by C57BL/10 parents. These results indicate that the developmental processes that lead to greater manipulatory behavior by adult BALB/c mice were not subject to influence by parents during the period from birth until weaning at 23 days of age. That parental influence during this period can be important is demonstrated by the results on visual exploration. There was no significant difference between the strains, but animals of both strains engaged in more visual exploration if reared by BALB/c than by C57BL/10 parents.

Much shorter experimental intervention was employed by Lindzey and co-workers (1960, 1963), who subjected mice of four inbred strains to the trauma of a loud, high-frequency auditory stimulus from the fourth through the seventh day of life. Animals were later tested in situations designed to assess emotionality, activity, and timidity. Their conclusion (1963) was that animals of

the C57BL strain have a very high sensitivity to noxious infantile stimulation, relative to the other strains investigated.

Levine and Wetzel (1963) studied the effects of manipulation during infancy on adult avoidance-learning performance in rats. The manipulation involved removal from the nest, three-minute detention in a compartment, and return to the nest. This treatment was administered once daily from birth through 21 days of age. Two different substrains of Long Evans rats showed an effect of treatment, with the manipulated animals making higher avoidance scores during the learning test. Another strain, Sprague-Dawley, showed no similar effect.

Application of the experimental condition was moved forward into the prenatal period by Thompson and Olan (1961). They studied the effects of injections of adrenalin to pregnant mice during the second or third trimester upon the adult activity of the offspring. The activity test was performed under normal conditions, and also under the stress of electrical foot-shock. In the A strain, offspring of injected mothers were more active under both normal and stress conditions of testing. BALB/c animals were unaffected by the treatment, and C57BL/6 mice showed only marginal effects when tested under the stress condition.

DeFries and his colleagues have explored further the role of prenatal stress in influencing adult behavior. The prenatal stress administered to the mothers consisted of daily exposure for three minutes to each of three stress conditions, beginning with the tenth postmating day and continuing throughout pregnancy. The stress conditions were forced swimming, exposure to intense white noise, and placement of the cage on a reciprocating shaker. In two reports (Wen and DeFries, 1964, DeFries, 1964) the effects of this treatment upon the adult open-field activity and emotional defecation of the fetuses were assessed. BALB/c and C57BL/6 mice were employed, and highly significant strain by treatment interaction was demonstrated. Subsequently, DeFries et al. (1967) have shown that the differential effects of the stress treatment are a function of both the maternal genotype and the fetal genotype. It was further demonstrated that injections of adrenalin did

not have the same effect as did the administration of the physical stress

One means of assessing the importance of maternal environment on development is to compare reciprocal F_1 hybrids between two strains of mice. Thus hybrids between the strains C57BL/6 and BALB/c have the same autosomal genotype regardless of whether their mother was a BALB/c and the father a C57BL/6 or the converse. In the one case, however, the fetuses will have developed in a BALB/c uterine environment, and in the other case in a C57BL/6 environment. DeFries (1964) studied reciprocal F_1 s of this kind, and the results illustrate the complexity of interactions that may occur. The prenatal maternal stress was found to result in a decrease in activity of F_1 hybrid offspring carried by C57BL mothers, which is an effect similar to that on inbred BALB/c offspring. On the other hand, the effect on F_1 hybrids carried by BALB/c females was similar to that on the C57BL strain.

The comparison of reciprocal F_1 hybrid litters is by definition constrained to hybrid groups. An assessment of maternal uterine environment effects on inbred strains may also be accomplished by the use of ovary transplant techniques. DeFries et al. (1967) transplanted ovaries from donors of the inbred strains BALB/c and C57BL/6 into F_1 hybrid recipients. Appropriate matings provided inbred offspring carried by either hybrid or inbred mothers. The very large differences in the adult activity levels of the BALB/c and C57BL animals were found, regardless of

whether the animals had developed in the uterine environment of a mother of identical genotype or in a hybrid.

SUMMARY AND CONCLUSIONS

The intent of this chapter has been to provide an introduction to the empirical data and theoretical perspectives of the field of genetics, and to provide, where possible, examples that demonstrate the effect of genetic variables on behavior. Behavioral phenotypes appear to be in no qualitative way distinct from the anatomical or physiological traits that constitute the bulk of the empirical data upon which the science of genetics is based. Examples of single locus influence have been shown, the methods of quantitative genetics have been examined and their application to continuously distributed behavioral traits has been reviewed, examples have been provided of the physiological and biochemical route through which the genes are expressed, and the role of genes in determining developmental sequence has been discussed.

Developmental behavioral genetics is of very recent origin, and there is yet to emerge a coherent body of knowledge. The work that has been done by the pioneering workers in this area, however, has demonstrated beyond question the importance of heredity in processes of behavioral development. It is extremely important that the future progress in this specialty be communicated to the general field of developmental psychology, and become an integral part of the empirical knowledge and theoretical framework of that field.

3. *Physical Growth*

J M TANNER

All the skills, aptitudes and emotions of the growing child are rooted in or conditioned by his bodily structure. Behind each stage of learning lies the development of essential cell assemblies in the brain, behind each social interaction lies a body image conditioned by the facts of size and early or late sexual maturation. It needs no arguing that a child psychologist should have some knowledge of the facts of physical growth, and especially of those facts which particularly affect the child's feeling and behavior. That girls mature earlier physically than boys is known by every schoolteacher, but that boys of 14 may be completely prepubescent or completely physically mature is unknown or forgotten by many. Both facts have profound effects on the psychology of the children and the sociology of the school.

The growth of the brain is, of course, of paramount importance to the psychologist, but unfortunately we know less about this than about any other organ. This is due to technical difficulties, at last slowly being overcome. One section of this chapter is devoted to brain growth, another to growth of the endocrine system.

A third section is called "the organization of the growth process." In it are discussed general problems such as the regulation of growth, the catch-up after a period of malnutrition or disease, the existence of critical or sensitive periods, the existence of discrete stages of growth, the importance of invariant sequences of events occurring at varying ages. These problems are important to the psychologist not only in themselves, but because the situation in physical growth is a model for similar situations believed or known to occur

in psychological development. The facts of physical growth are easier to be sure of than those of mental development, hence the models from this field have a concreteness and certainty that the mental equivalents may still lack. Thus this chapter has both factual and theoretical importance for the psychologist-reader.

I THE HUMAN GROWTH CURVE

Figure 1 shows the most famous of all records of human growth. It concerns the height of a single boy, measured every six months from birth to 18 years. This is the oldest longitudinal record in existence, and it remains, for our purposes of illustration, one of the best. It was made during the years 1759-1777 by Count Philibert de Montbeillard on his son and it was published by Buffon in a supplement to the *Histoire Naturelle*.

In Fig 1a is plotted the height attained at successive ages, in 1b are shown the increments in height from one age to the next expressed as the rate of growth per year. If we think of growth as a form of motion, then the upper curve is one of distance traveled, the lower curve one of velocity. The velocity or rate of growth naturally reflects the child's state at any particular time better than does the distance achieved, which depends largely on how much the child has grown in all the preceding years. The blood and tissue concentrations of those substances whose amounts change with age are thus more likely to run parallel to the velocity rather than to the distance curve. In some circumstances, indeed, it is the acceleration rather than the velocity curve which best reflects physiological events,

Fig 1 Growth in height of de Montbeillard's son from birth to 18 years, 1759-1777 (a) Distance curve, height attained at each age (b) Velocity curve, increments in height from year to year (From Tanner, 1962, data from Scammon, 1927)

it is probable, for example, that the great increase in secretion of the endocrine glands at adolescence is manifested most clearly in acceleration of growth (see Fig 18)

Figure 1b shows that in general the velocity of growth decreases from birth (and actually from as early as the fourth month of fetal life, see Section II), but that this decrease is interrupted shortly before the end of the growth period. At this time, from 13 to 15 years in

this particular boy, there is a marked acceleration of growth, called the adolescent growth spurt (Also, horribly, called the circumpubertal growth spurt. Some writers distinguish sharply the terms "adolescence" and "puberty," though not all who do so agree in their distinctions. Some use puberty to refer to physical changes, adolescence to refer to psychosocial ones. I have used the terms interchangeably in this chapter.) From birth until

age 4 or 5 the rate of growth in height declines rapidly, and then the decline, or deceleration, gets gradually less, so that in some children the velocity is practically constant from 5 or 6 up to the beginning of the adolescent spurt. A slight increase in velocity is sometimes said to occur between about 6 and 8 years, providing a second wave on the general velocity curve. Although Fig. 1 seems to show its presence, examination of many other individual records from age 3 to 13 fails to reveal it in the great majority, if it occurs at all, it is only in a minority of children.

As the points of Fig. 1 show, growth is in general a very regular process. Contrary to opinions still sometimes met, growth in height does not proceed by fits and starts, nor does growth in upward dimensions alternate with growth in transverse or, more ominously, anteroposterior ones. The more carefully these measurements are taken, with precautions, for example, to minimize the decrease in height that occurs during the day for postural reasons, the more regular does the succession of points in the graph become. Figure 2 shows the fit of a smooth mathematical curve to a series of measurements taken on a child by the same observer every 6 months from age $3\frac{1}{2}$ to 10. None of the points deviates from the line by an amount more than measuring error. This is generally

true, although in some children regular seasonal variations (discussed later) superimpose an added 6-month rhythm about the curve. There is no evidence for "stages" of growth in height (or any other physical measurement) except for the spurt associated with adolescence. Perhaps increments of growth at the cellular level are discontinuous, but at the level of bodily measurements, even of single bones measured by X-rays, we can only discern complete continuity, with a velocity that changes gradually from one age to another.

Many attempts have been made to find mathematical curves which fit, and thus summarize, human and animal growth data. Most have ended in disillusion or fantasy, disillusion because fresh data failed to conform to them, or fantasy because the system eventually contained so many parameters that it became impossible to interpret them biologically. What is needed is a curve or curves with relatively few constants, each capable of being interpreted in a biologically meaningful way. The fit to empirical data must be adequate, of course, within the limits of measuring error. Part of the difficulty arises because the measurements usually taken are themselves biologically complex. Stature, for example, consists of leg length and trunk length and head height, all of which have rather different growth curves. Even with such relatively

Fig. 2 Curve of form $y = a + bt + c \log t$ fitted to stature measurements taken every 6 months by R. H. Whitehouse on a girl from age $3\frac{1}{2}$ to 10. Harpenden Growth Study (From Israelsohn, 1960)

homogeneous measurements as humerus length or calf-muscle width, it is not clear what purely biological assumptions should be made as the basis for the form of the curve. The assumption that cells are continuously dividing leads to a different formulation from the assumption that cells are adding constant amounts of nondividing material, or amounts of material at rates varying from one age period to another.

But fitting a curve to the individual values is the only way of extracting the maximum information about an individual's growth from the measurement data. This fact becomes increasingly inescapable when the effect of environmental circumstances on growth rate (e.g., illness on height growth) is investigated, or when two different measurements are being compared for the consistency of each as the child grows up. The individual's consistency can only be measured by deviations from his own growth curve. A change of rank order of two individuals from one age to another in a measurement may represent not inconsistency but consistently differing rates of change, one individual having a small velocity in the measurement, and the other individual a larger one.

More than one curve is needed to fit the postnatal age range. It seems that two curves may suffice, at least for many measurements such as height and weight. A curve of the form

$$y = a + bt + c \log t$$

where y is the measurement at age t , appears to fit well from a few months after birth to the beginning of adolescence. This is the curve shown in Fig. 2. The adolescent spurt is fitted well by the Gompertz curve, a skew S-shaped exponential, of mathematical form

$$y = Ke^{-e^{-1+mt}}$$

which expresses the assumption that in equal small intervals of time the organism loses equal proportions of its remaining power to grow.

Types of Growth Data

The curves just discussed have to be fitted to data on single individuals. Yearly averages derived from different children each measured once only do not, in general, give the

same curve. Thus the distinction between the two sorts of investigation is very important. The method of study using the same child at each age is called *longitudinal*, that using different children at each age is called *cross-sectional*. In a cross-sectional study each child is measured once only and all the children at age 10, for example, are different from those at age 9. A study may be longitudinal over any number of years; there are short-term longitudinal studies extending from age 3 to 5, for instance, and full birth-to-maturity longitudinal studies in which the children may be examined once, twice, or even more times every year from birth until 20 or over.

In practice it is always impossible to measure exactly the same group of children every year for a prolonged period; inevitably some children leave the study and others, if that is desired, join it. A study in which this happens is called a *mixed longitudinal* study, and special statistical techniques are needed to get the maximum information out of its data. In the past this has not always been understood, with the result that three-quarters and more of the useful information of mixed studies has been thrown away, or, to put it differently, that twenty times more children have been used to establish a mean velocity to within certain statistical limits than were actually required. One particular type of mixed study is that in which a number of relatively short-term longitudinal groups are interlocked, here we may have groups of 0-6, 5-11, 10-16, and 15-20 to cover the whole age range. Problems arise at the "joins" unless the sampling has been remarkably good, but the whole age range is covered for estimates of mean yearly velocity in the research time of five years.

Both cross-sectional and longitudinal studies have their uses, but they do not give the same information and cannot be dealt with in the same way. Cross-sectional surveys are obviously cheaper and more quickly done, and can include far larger numbers of children. They tell us a good deal about the distance curve of growth and it is essential to have them as part-basis for constructing standards for height and weight and other measurements in a given community. Periodic cross-sectional surveys are valuable in assessing the nutritional progress of a country or a socioeconomic group and the health of the child population as a whole. But they have one

great drawback they can never reveal individual differences in rate of growth or in the timing of particular phases such as the adolescent growth spurt. It is these individual rate differences which chiefly throw light on the genetical control of growth and on the correlation of growth with psychological de-

velopment, educational achievement, and social behavior. Longitudinal studies are laborious and time consuming, they demand great perseverance on the part of those who make them and those who take part in them, and they demand very high technical standards, since in the calculation of a growth increment

Fig 3 The relation between individual and mean velocities during the adolescent spurt (a) The individual height velocity curves of five boys of the Harpenden Growth Study (solid lines) with the mean curve (dashed) constructed by averaging their values at each age (b) The same curves all plotted according to their peak height velocity (From Tanner, Whitehouse, and Takashi, 1966)

from one occasion to the next two errors of measurement occur. They demand also a sequential approach to problems, with all past data fully computerized and available for analysis in relation to a specific question at any time. The evidence of the past suggests that unless accompanied by cross-sectional surveys and animal experimentation, as they are at the Fels Research Institute in Yellow Springs, Ohio and the Department of Growth and Development at London University Institute of Child Health, they can sink over the years into sterile deserts of number-collecting. But they are indispensable.

Cross-sectional data can in some important respects be misleading. Figure 3 illustrates the effect on "average" figures produced by the individual differences in the age at which the adolescent spurt begins. Figure 3a shows a series of individual velocity curves from 10 to 18 years, each individual starting his spurt at a different age. The average of these curves, obtained simply by treating the

values cross-sectionally and adding them up at age 10, 11, 12, etc., and dividing by 5, is shown by the dashed line. This line in no way characterizes the "average" velocity curve, on the contrary, it is a travesty of it. It smooths out the adolescent spurt, spreading it along the time axis. It does not take account of the "phase-differences" between the individual curves. Figure 3b shows the same individual curves, but arranged so that their peak velocities coincide, the average curve then characterizes the group in a proper manner. In passing from Fig 3a to 3b the time-scale has been altered so that in 3b the curves are plotted not against chronological age but against a measure which arranges the children according to how far they have traveled along their course of development, in other words, they are arranged according to their true developmental or physiological growth status. This is nearly always the appropriate method in analyzing longitudinal data, especially at adolescence. It is just this

Fig 4 Typical-individual height-attained curves for boys and girls (Supine length to the age of 2). Integrated curves of Fig 5 (From Tanner, Whitehouse, and Fakaishi, 1966)

Fig 5 Typical-individual velocity curves for supine length or height in boys and girls. These curves represent the velocity of the typical boy and girl at any given instant (From Tanner, Whitehouse, and Takaishi, 1966)

sort of difficulty that curve-fitting overcomes so well, one parameter representing the peak velocity reached, another the age at which it occurred, and so on.

Averages computed from cross-sectional data, however, inevitably produce velocity curves of this flattened, distorted type, and, equally, distance curves show the distortion by not rising sufficiently rapidly at adolescence.

Until recently all the published height and weight standards used in hospitals and schools incorporated this distortion. However, it is possible to construct curves whose fiftieth percentile represents the actual growth of a typical individual by taking the shape of the curve from individual longitudinal data, and the absolute values for the beginning and end from large cross-sectional surveys (Tanner, Whitehouse, and Takaishi, 1966). Figures 4

and 5 show height-attained and height-velocity curves for the "typical" boy and girl in Britain in 1965, determined in this way. By "typical" is meant that boy or girl who has the mean birth length, grows always at the mean velocity, has the peak of the adolescent growth spurt at the mean age, and, finally, reaches the mean adult height at the mean age of cessation of growth. There is of course a certain danger in showing such a smooth, average curve, for measurements on a single individual are naturally less regular, however expert the measurer. Practically no individual follows the fiftieth percentile curve of Figs 4 and 5, but most have the same shaped curve. Some individuals, mostly late-maturing boys, however, seem to have a slight dip in the velocity curve just before the adolescent spurt starts. These are such a small minority that they have been ignored when the typical-in-

dividual curves were constructed. They remain an interesting entry to further work on the human growth curve.

Boys' and Girls' Height Curves

Figures 4 and 5 show the height curves from birth to maturity. Up to age 2 the child is measured lying down on his back. One examiner holds his head in contact with a fixed board and a second person stretches him out to his maximum length and then brings a moving board into contact with his heels. This measurement is called supine length, and averages about 1 cm more than the measurement of standing height taken in the same child, even when, as in the best techniques, the child is urged to stretch upward to full height and is aided in doing so by a measure applying gentle upward pressure to his mastoid processes. This causes the break in the line in Fig. 4 at age 2. Figure 4 shows the typical girl as slightly shorter than the typical boy at all ages until adolescence. She becomes taller shortly after age 11.0 because her adolescent spurt takes place 2 years earlier than the boy's. At age 14.0 she is surpassed again in height by the typical boy, whose adolescent spurt has now started, whereas hers is nearly finished. In the same way, the typical girl weighs a little less than the boy at birth, equals him at age 8, becomes heavier at age 9 or 10, and remains so till about age 14½.

The velocity curves given in Fig. 5 show these processes more clearly. At birth the typical boy is growing very slightly faster than the typical girl, but the velocities become equal at about 7 months and then the girl grows faster to 4 years. From then till adolescence no difference in velocity can be detected. The sex difference is best thought of, perhaps, in terms of acceleration; the boy decelerating harder than the girl over the first 4 years (see also Deming, 1957; Deming and Washburn, 1963). In Britain in 1965 the typical girl begins the adolescent height spurt at about age 10.5 and reaches peak height velocity at approximately 12.0. The boy begins his spurt and reaches his peak just 2 years later. The boys' peak is higher than the girls', averaging in our data 10.3 ± 0.2 cm/year compared with the girls' 9.0 ± 0.2 cm/year (as "instantaneous" peaks, i.e., peaks obtained by fitting smoothed curves to the observations, the velocities over the whole years which in-

clude the peak moment are naturally less, averaging 9.5 cm/year for boys and 8.4 cm/year for girls).

Girls are always in advance of boys (i.e., closer to their final mature status), even at birth, this very important sex dimorphism is considered in more detail in Section IV.

Growth Curves of Different Tissues and Different Parts of the Body

Most measurements of the body follow approximately the growth curve described for height. The great majority of skeletal and muscular dimensions grow in this manner, and so also do the internal organs such as liver, spleen, and kidneys. But some exceptions exist, most notably the brain and skull, the reproductive organs, the lymphoid tissue of the tonsils, adenoids, and intestines, and the subcutaneous fat.

In Fig. 6 these differences are shown, using the size attained by various tissues as a percentage of the birth-to-maturity increment. Height follows the "general" curve. The reproductive organs, internal and external, have a slow prepubescent growth, followed by a very large adolescent spurt; they are less sensitive than the skeleton to one set of hormones and more sensitive to another.

The brain, together with the skull covering it and the eyes and ears, develops earlier than any other part of the body and thus has a characteristic postnatal curve (Brain growth is further discussed in Section VI). If the brain has any adolescent spurt at all, it is a very small one. A small but definite spurt occurs in head length and breadth, but all or most of this is due to thickening of the skull bones and the scalp and development of the air sinuses. The dimensions of the face follow a path somewhat closer to the general curve. There is a considerable adolescent spurt, especially in the mandible, resulting in the jaw becoming longer and more projecting, the profile straighter, and the chin more pointed. But, as always in growth, there are considerable individual differences, to the point that a few children have no detectable spurt at all in some face measurements.

The eye probably has a slight adolescent spurt, although present data are not sufficiently accurate to make this certain. Very likely it is this that is responsible for the

Fig 6 Growth curves of different parts and tissues of the body, showing the four chief types. All the curves are of size attained, and plotted as percent of total gain from birth to 20 years, so that size at age 20 is 100 on the vertical scale (From Tanner, 1962, redrawn from Scammon, 1930)

Lymphoid type thymus, lymph nodes, intestinal lymph masses *Brain and head type* brain and its parts, dura spinal cord, optic apparatus, cranial dimensions *General type* body as a whole, external dimensions (except head) respiratory and digestive organs, kidneys, aortic and pulmonary trunks, musculature, blood volume *Reproductive type* testis, ovary, epididymis, prostate, seminal vesicles, Fallopian tubes

increase in frequency of short-sightedness in children which occurs at the time of puberty. Although the degree of myopia increases continuously from at least age 6 to maturity, a particularly rapid rate of change occurs at about 11 to 12 in girls and 13 to 14 in boys, and this would be expected if there was a rather greater spurt in the axial dimension of the eye than in its vertical dimension (for references see Tanner, 1962).

The lymphoid tissue has quite a different growth curve from the rest of the body (see Fig 6). It reaches its maximum amount before adolescence and then, probably under the direct influence of sex hormones, declines to its adult value.

The subcutaneous fat layer also has a curve of its own, of a slightly complicated sort. Its thickness can be measured either by X-rays or, more simply, at certain sites in the body, by picking up a fold of skin and fat between the thumb and forefinger and measuring its thickness with a special, constant-pressure caliper. Figure 7 shows the distance curves of skinfolds taken halfway down the back of the arm (triceps) and at the back of the chest, just below the shoulder blade (subscapular). Subcutaneous fat begins to be laid down in the fetus at about 34 weeks postmenstrual age, increases from then till birth and from birth to about 9 months (This is in the average child, the peak may

be reached as early as 6 months or as late as 12 or 15. After 9 months, when the velocity of fat gain is zero, the fat actually decreases, that is, has a negative velocity, until age 6 to 8 when it begins to increase once more, in the pre-adolescent fat spurt comprehensively described by Stolz and Stolz (1951). Girls have a little more fat than boys at birth, and the difference becomes more marked during the period of loss, which is not so great in girls as in boys. From 8 years on the curves for girls and boys diverge more radically, as do the curves for limb and body fat. At adolescence the limb fat in boys decreases (see triceps, Fig 7), the body fat shows a temporary slowing down of gain, but no actual loss in the average boy. In girls there is a slight halting of the limb-fat gain at adolescence, but no loss, the trunk-fat shows only a steady rise until adulthood.

Postadolescent Growth Growth, even of the skeleton, does not entirely cease at the end of the adolescent period. In man, in contrast to some other mammals such as the rat,

the epiphyses of the long bones close completely and cannot then be made to grow again. But bones that grow by surface deposition may continue. The vertebral column continues to grow until about age 30, by apposition of bone to the tops and bottoms of the vertebral bodies. Thus height increases by a small amount, on average 3 to 5 mm. From about 30 to 45 it remains stationary, and then it begins to decline (Buchi, 1950). Head length and breadth and facial diameters increase slightly throughout life, and so does the width of bones in the leg and in the hand, in both sexes (Garn, Rohmann, Wagner, and Ascoli, 1967). For practical purposes, however, it is useful to have an age at which we may say that growth in stature virtually ceases, that is, after which only some 2% is added. At present in North America and northwest Europe the average boy stops growing, in this sense, at 17.5 and the average girl at 15.5 years, with a normal variation for different individuals of about 2 years on either side of these averages.

Fig 7 Distance curve of subcutaneous tissue measured by Harpenden skinfold calipers over triceps and under scapula. Logarithmic transformation units. Data 0-1 year, pure longitudinal, 74 boys and 65 girls (Brussels Child Study, Graffar, Asiel and Corbier, unpub.), 2-6 years, London Child Study Center (Tanner, unpub.) with pure longitudinal core 4-6 years of 59 boys and 57 girls, actual mean increments subtracted or added to get means at 2 and 3, 5-16 years, London County Council (Scott, 1961) cross-sectional, 1000 to 1600 of each sex at each year of age from 5 to 14, 500 at 15, 250 at 16 (From Tanner, 1962).

Fig 8 Weight velocity curve for the mouse Curve 1 sexes combined, cross-sectional, from MacDowell, Allen, and MacDowell (1927) Curves 2 and 3, males (18) and females (18), pure longitudinal, MacArthur large strain (Butler and Metrakos, 1950) Time of puberty from Engle and Rosasco (1927) and Flux (1954) (From Tanner, 1962)

The Human Growth Curve as a Primate Characteristic

The characteristic shape* of the human growth curve is shared by apes and monkeys (or at least by chimpanzees and rhesus, the only species for which we have adequate data) But it is apparently a distinctive primate characteristic, for neither rodents nor cattle have curves resembling it

In Figs 8 and 9 are shown the velocity curves for body weight of mice and chimpanzees (weight has to be used, since so few data on length exist) In the mouse, as in the rat, there is little interval between weaning and puberty, and no visible adolescent spurt because there is no period of low velocity between birth and maturity In terms of the maturation of their organs, mouse and rat are born earlier in development than is man The peak velocity of the mouse's weight curve occurs at a time that corresponds closely, by this organ-maturation calendar, with birth in man, which is when

the first peak of man's weight velocity curve occurs In the chimpanzee (Fig 9), on the other hand, the curve resembles entirely that of man The first peak velocity of weight must be shortly before or at birth, but this is followed by a gradual decrease of velocity during the long interval between weaning and puberty The rhesus monkey has a similar curve, though with less time intervening between weaning and puberty The magnitude of the adolescent spurt, and in particular the degree of sex dimorphism occurring during it, varies in primates from species to species

The prolongation of the time between weaning and puberty appears to be an evolutionary step among the mammals, taken by the primates, and reaching its most pronounced development in man The increased time necessary for the maturing of the primate brain has been sandwiched into this period At least some of the evolutionary reasons for this are not hard to find It is probably advantageous for learning, and especially learning to cooperate in group or

family life, to take place while the individual remains relatively docile and before he comes into sexual competition with adult males

Measurements and Methods

This is not the place to discuss what measurements are most important in growth studies, nor to detail the manner in which they should be made. Height and weight are the traditional basic measurements, and height is indeed perhaps the most generally useful one. But it is not the best for all purposes, for if we are interested in comparing humans with other primates or with less closely related mammals, we must dissociate the limb and trunk and compare sitting height or crown-rump length. Weight is easier to measure but much less useful, since it consists of a conglomerate of all the tissues, which, as we have seen, do not all have the same growth curves. Thus if a child is putting on weight, this may be because of muscular and skeletal growth or fat growth only. Failure to gain weight, or actual loss of weight in an older child, may signify nothing except a better attention to diet and exercise, whereas failure to gain height or muscle would call for an immediate investigation.

Some children and adults who are "over-weight" by the traditional weight-for-height tables are simply athletes with heavy muscles. If one wants to know if a child is fat, the best thing is to measure the amount of subcutaneous fat directly.

Other measurements frequently made are sitting height (giving leg length by subtraction from stature), shoulder and hip width, head length and breadth, arm and calf circumference, skinfolds, and widths across the elbow and knee. Two internationally used series or batteries of measurements are available. One is the baseline of the birth-to-maturity longitudinal studies sponsored by the International Children's Center, Paris, made concurrently in Brussels, London, Louisville, Paris, Stockholm, and Zurich, and matched by exactly similar studies in Prague, Helsinki, Dakar, Kampala, and elsewhere. The 13 basic measurements and the manner of making each are given in Falkner (1960). Photographs showing measurement technique can be seen in Tanner (1964). The second international battery is the rather more ambitious measurement schedule laid down for use of all studies of growth and physique made in association with the International Bio-

Fig 9 Weight velocity curve for the chimpanzee. Actual increments from Grether and Yerkes (1940). Menarche from Young and Yerkes (1943) and Gavan (1953), average 8.8 years, range 7.0 to 10.8 (From Tanner, 1952)

logical Program Two schedules are given, one comprising 21 measurements, the other 37 (Tanner, Hiernaux, and Jarman, 1968) This IBP Handbook also gives details of radiographic techniques for demonstrating bone muscle and fat These are also illustrated and described in Tanner (1964)

The International Children's Center Studies are designed longitudinally and call for the children to be examined at 1, 3, 6, 9, 12, 18, and 24 months and yearly thereafter Age limits are laid down for these examinations, thus at 3 to 18 months the child should be within ± 7 days of the required date and at later ages within ± 14 days In practice the use of such limits turns out to be more important for cross-sectional surveys than for longitudinal studies where individual curve-fitting may be done whatever the dates of examination There is, however, an apparently small but significant technical point Calculating velocities for individual children examined at varying intervals is intolerably difficult if the usual system of age in years and months is used It is much simpler to use *decimal age*, that is, a calendar which operates in decimals of a year In such a calendar June 1, 1968 is 68.414, for example If a child's birth date is August 16, 1961 (61.622), his age on June 1, 1968 would be simply $68.414 - 61.622 = 6.79$ (rounded) Increments of age from one examination to the next are easily calculated by subtraction and rates of growth are calculated by simple division A table of decimals of a year can be found in the IBP Handbook or in Tanner, Whitehouse, and Takaishi (1966)

A last point concerns the reporting of growth data Confusion still arises between means referring to, say, children all aged exactly 6.0, children aged 6.0 to 6.99, and children aged 5.5 to 6.49 The best terminology is to label the means of these age groups as 6.0, 6+, and 6 \pm , respectively

II PRENATAL GROWTH

The period of prenatal growth is vitally important to the child's future well-being, yet it is the period about which, inevitably, we know least For the first two-thirds of pregnancy we have to rely on cross-sectional studies, and to a large extent on embryos and fetuses expelled from the uterus because

one or the other was abnormal For later fetal life we can study infants born prematurely, making the assumption that these children have grown before birth and will grow after it in exactly the same way as children who remain in the uterus the average length of time Though this seems to be a hazardous assumption, it is probably justified, if children with certain abnormalities are excluded

Our ignorance begins at the beginning, for we do not know what forces are responsible for selecting out of the millions of sperm the one which fertilizes the ovum Fertilization takes place in one of the tubes which lead from the ovaries to the uterus The fertilized egg spends about seven days drifting down the tube and floating in the uterine cavity before implantation into the wall of the uterus takes place During this time the cells divide steadily, so that when it is ready for implantation, the blastocyst, as it is called, consists of several dozen cells Blastocysts can be washed out of the tube and implanted in a foster-mother, and in animals this technique has been used both for examining the effect of different kinds of uterine environment on development (McLaren and Michie, 1956) and for transporting by air the fetuses of large animals packaged, temporarily, in the uterus of small ones

After implantation the outer layer of the blastocyst undergoes a series of changes culminating in the formation of the placenta, and a small portion of the inner layer develops into the embryo The period of the embryo is considered to begin two weeks after fertilization and ends eight weeks after fertilization, when the child, now recognizably human, with arms and legs, a heart that beats, and a nervous system that shows the beginnings of reflex responses to tactile stimuli, is called a fetus At this age it is about 3 cm long

This is a hazardous period, and considerably more ova are fertilized than come to fruition Probably about 30% of embryos are aborted, usually without the mothers' knowledge This is due in most cases to abnormalities of development, either of the embryo or of its protective and nutritive surrounding structures For example, chromosomal abnormalities are present in between 3 and 4% of fertilized ova, but in only $\frac{1}{4}\%$ of newborns Thus about 90% of all conceptuses with these abnormalities are rejected as early spontane-

ous abortions. Lesser degrees of abnormality may result in a viable fetus and child, but one which grows less than normal. An example of this is the child with the chromosomal disorder of triple-21, discussed in Chapter 2 of this book.

The reckoning of age in the prenatal period presents a problem. Traditionally and because we have no better way, age is counted from the first day of the last menstrual period. This occurs on average two weeks before fertilization. Thus the most frequent age at birth is 280 days or 40 weeks, reckoned as "postmenstrual age," but it represents only 38 weeks of true fetal age. There are difficulties in individual cases, however, the interval from menstruation to fertilization varies considerably, and worse, menstrual bleeding, or something like it, may continue in some women for one or even two months after fertilization.

Thus reliable growth curves of the fetus are hard to come by. Figure 10 shows the distance and velocity curves of body length, so far as it may be measured, in prenatal life and for 2 years after birth. The peak velocity

Fig 10 Distance (a) and velocity (b) curves for growth in body length in prenatal and early postnatal period. Cross-sectional data of His and Russow. (Redrawn from Thompson, 1942)

is reached at about 4 months postmenstrual age. In the embryonic period the velocity is not very great. During these first 2 months differentiation of the originally homogeneous whole into regions, such as head, arm, and so forth, occurs, as does histogenesis, the differentiation of cells into specialized tissues such as muscle or nerve. At the same time each region is molded, by differential growth of cells or by cell migration, into a definite shape. This process, known as morphogenesis, continues right up to adulthood and, indeed, in some parts of the body, into old age. But the major part of it is completed by the eighth postmenstrual week.

The great rate of growth of the fetus compared with that of the child is largely due to the fact that cells are still multiplying. The proportion of cells undergoing mitosis in any tissue becomes progressively less as the fetus gets older, and it is generally thought that few if any new nerve cells (apart from neuroglia) and only a small proportion of new muscle cells appear after 6 fetal months, the time when the velocity in linear dimensions is sharply dropping. The muscle and nerve cells of the fetus are considerably different in appearance from those of the child or adult. Both have little cytoplasm around the nucleus. In the muscle there is a great amount of intercellular substance and a much higher proportion of water than in mature muscle. The later fetal and the postnatal growth of muscle consists chiefly of building up the cytoplasm of the muscle cells, salts are incorporated and the contractile proteins are formed. The cells become bigger, the intercellular substance largely disappears, the concentration of water decreases. This process continues quite actively up to about 3 years of age and slowly thereafter, at adolescence it briefly speeds up again, particularly in boys, under the influence of androgenic hormones. In the nerve cells cytoplasm is added, nucleoprotein bodies appear, and axons and dendrites grow. Thus postnatal growth is, for at least some tissues, chiefly a period of development and enlargement of existing cells, whereas early fetal life is a period of the division and addition of new cells.

The Effect of the Uterine Environment

Growth in weight of the fetus follows the same general pattern as growth in length, ex-

Fig 11 Velocity of growth in weight of singleton children Prenatal curve from data of McKeown and Record (1952) on birth-weights of live-born children delivered before 40 weeks of gestation Postnatal data from Ministry of Health (1959), mixed longitudinal data (their Table VII) Dashed line shows estimate of velocity immediately before and after birth, showing catch-up (From Tanner, 1963)

cept that the peak velocity is reached much later, at approximately 34.0 weeks postmenstrual (Gruenwald, 1967). There is considerable evidence that from about 34 or 36 weeks on the rate of growth of the fetus slows down due to the influence of the maternal uterus, whose available space is by then becoming fully occupied. Twins slow down earlier, when their combined weight is approximately the 36-week weight of the singleton fetus (McKeown and Record, 1952, 1953, Naeye, Benirschke, Hagstrom, and Marcus, 1966). In Fig 11 is plotted the velocity curve for mean weight of live-born singletons of gestation period 24 to 40 weeks, with a postnatal curve from a large-scale mixed longitudinal study of a similar population (Ministry of Health, 1959). The velocity rises in the immediate postbirth period to make a peak which would quite naturally join with the prebirth peak to make a smooth velocity curve without the dip in the last few weeks before birth. The increase in velocity after birth represents a catch-up (see Section

VII) on the part of those newborns who have been most held up in the uterus. Thus there is a significant negative correlation between length at birth and length increment during the first year, and also between weight and weight increment.

This slowing-down mechanism enables a genetically large child developing in the uterus of a small mother to be successfully delivered. It operates in many species of animal, the most dramatic demonstration was made by crossing reciprocally a large Shire horse and a small Shetland pony. The pair in which the mother was a Shire had a large newborn foal, and the pair in which the mother was Shetland had a small foal. But both foals were the same size after a few months, and both ended about halfway between their parents. The same has been shown in cattle crosses (Dickinson, 1960). In man the correlation between length at birth and adult height is only about 0.3, but it rises sharply during the first year and between length at age 2 and adult height is

nearly 8 (Tanner, Healy, Lockhart, MacKenzie, and Whitehouse, 1956) These figures also reflect maternal control of the newborn size

How this control is exercised is not clear The placenta grows at first more rapidly than the fetus, but then it grows more slowly so that the placenta/fetus ratio falls from about 30 weeks on It may be that the placenta simply cannot increase its capacity to supply nutriment sufficiently to sustain the rapid 34-week fetal velocity In mice and guinea pigs it seems likely that the limiting factor is a hemodynamic one, the size of the placenta being dependent on the pressure at which the maternal blood reaches it, and the size of the fetus depending, in turn, on the size of the placenta (McLaren, 1965) Whether this is also important in man is not yet known

Poor environmental circumstances, especially of nutrition, result in lowered birth weight in the human This seems chiefly to be due to a reduced rate of growth in the last 2 to 4 weeks of fetal life, for weights of babies born at 36 or 38 weeks in various parts of the world under various circumstances are rather similar (Gruenwald, 1967) Mothers who due to adverse circumstances in their own childhood have not achieved their full growth potential may produce smaller fetuses than they would have had they grown up under better circumstances Thus two generations or even more may be needed to undo the effect of poor environmental circumstances on birth weight

So-Called "Premature" Babies

Some babies are born earlier than others and they naturally tend to be smaller Until recently all babies under the birth weight of 2500 grams (5½ pounds) were designated "premature" whatever in fact their physiological state or gestation period This definition (promulgated by WHO in 1948) did a lot of harm and has now been dropped, the word premature has gone out of scientific use Babies less than 2500 grams at birth (WHO 1961, but a better usage is 2000 grams) are called low-birth-weight infants, babies born after a shorter than usual period in the uterus are called short-gestation-period infants Standards exist for comparing the birth weight of a short-gestation child with

that of others of similar gestation If the child's weight on this basis is low, he is called small-for-dates

These distinctions are important Low-birth-weight children grow faster than others during the first two years, catching up somewhat, but they do not reach the height or weight of normal children growing up under similar environmental circumstances by age 5 or probably ever Nor do they on average achieve the same level of ability in tests of intelligence, though here also they show catch-up in the first two years (Drillien, 1964) The deficits in both size and ability increase as the birth weight decreases, children between 2000 and 2500 grams at birth show little impairment of ability and only a slight size deficit A considerable proportion of those under 2000 grams, however, have some mental or neurological defect Evidently many of the 2000 to 2500-gram babies are simply small babies born after a normal gestation to genetically small mothers, whereas most of those below 2000 grams have suffered some developmental difficulty It is interesting that mothers of these babies have a higher proportion of abnormal outcomes in other conceptions also than do mothers of larger infants

Clearly the prognosis for a small child born after the normal length gestation and an equally small child born after a shortened gestation may be very different Leaving the uterus early is not in itself necessarily deleterious, whereas growing less than normally during a full uterine stay implies pathology of fetus, placenta, or mother

Birth as a Happening

For some physiological functions birth signifies upheaval and change, often associated with a particular vulnerability But it is important to realize that for very many others birth is an incident without much significance in a steadily maturing and changing program of events

The respiratory and the cardiovascular systems are the ones most altered by the fact of birth Failure to establish satisfactory respiration during the crucial period just after birth is a common cause of neonatal death and of brain injury among survivors The newborn infant, however, has a much greater capacity to survive straightforward anoxia

undamaged than do children or adults, and we are moving toward the view that in many cases it is pre-existing brain damage, of developmental or uterine origin, which is the reason for failure to initiate respiration, or failure apparently to survive a period of anoxia. "Almost all medical literature still equates failure to breathe at birth with 'birth injury' placing the damage at the time of delivery. The evidence suggests that pre-existing brain damage interferes with the ability to adjust to extra-uterine life and to initiate respiration" (Knobloch and Pasamanick, 1962). Drillien (1964) remarks of her own comprehensive study that the more severe defects originate usually at an early stage of fetal development rather than from damage to a potentially normal nervous system occurring in the last three months of pregnancy or during delivery. Differences in later behavior are found between children who have been subjected to certain obstetric hazards and those who have not, however, and these may be wholly or partly due to minimal brain damage occurring at the time of delivery.

Some enzyme systems are equally sharply affected by the fact of birth. Thus in rabbits there is a sudden rise in glucose-6-phosphatase in the liver at birth and not before, whether birth is induced early, occurs normally, or is late (Dawkins, 1961). Other animals also show a rise in this enzyme at birth. This is readily accounted for. The enzyme catalyzes the breakdown of glycogen to glucose, and during the last part of fetal life many mammals store a lot of glycogen in the liver. Just after birth there is great need of glucose in the blood and tissues, pending the full establishment of lactation, and the enzymic events are adjusted in a way which brings this about.

On the other hand, numerous enzymes exist with time courses of development which are quite independent of birth (see Sereni and Principi, 1965). A well-known example is the switch from production of fetal hemoglobin to adult hemoglobin. These are forms of hemoglobin with slightly different molecular structures. A gradual switch in production occurs, so that the percentage of fetal hemoglobin begins dropping from about the thirty-sixth postmenstrual week. The switch is not due to birth, however, because the fetal per-

centage remains high in prematurely born babies and is low in those who are post-maturely born (Jonxis, 1965). Thus in this, as in other respects, the prematurely born has to await the striking of some differently regulated biological clock.

Most importantly, the maturation of the nervous system seems to be little affected by the fact of birth. The electroencephalogram of an infant born prematurely at 28 weeks will 6 weeks later be much the same as that of an infant born at 34 weeks (Dieyfus-Brisac, 1966, Minkowski, 1966). Birth also does not influence the date of appearance of conditioned reflexes (Papoušek, 1961) nor the stages of motor behavior elicited by detailed neurological examination. According to Daigassies (1966) the development of this behavior occurs in a prematurely born infant just "as if birth before term did not perceptibly alter the course of neurological maturation [(The schedule)] is adhered to just as closely in an incubator as in utero."

III GROWTH AND DEVELOPMENT AT ADOLESCENCE

After birth the growth rate of most body tissues falls steadily, the fall being swift in the first two or three years and slower thereafter. The rate of growth in height decreases slowly from an average of 6.5 cm/year at age 5.0 to about 5.0 cm/year just before the adolescent spurt begins. Weight velocity is almost constant from age 3 to puberty (rising from an average of 2.0 kg/year to about 2.7 kg/year), since the increase in fat velocity balances the drop in velocity of muscular and skeletal dimensions. Body shape continues to change, since the rate of growth of some parts, such as the legs and arms, is greater than the rate of growth of others, such as the trunk. But the change is a steady one, a smoothly continuous development of the final prepubescent physique rather than any passage through a series of separate stages.

The Adolescent Growth Spurt

At puberty, a very considerable change in growth rate occurs. For a year or more the velocity of growth approximately doubles. A boy is likely to be growing at a rate he last experienced at about age 2. During the year

which includes the moment of peak height velocity a boy usually grows between 7 and 12 cm and a girl between 6 and 11 cm. Children who have their peak early reach a higher peak than those who have it late, the correlation between peak height velocity and the age at which it is reached being about -0.45 (this is visible in the lines of Fig 3). The average age at which the peak occurs varies more from one population to another than does the magnitude of the peak, depending on environmental and perhaps genetic circumstances. In moderately well-off children in West Europe the peak is reached on average at about 14.0 in boys and 12.0 in girls, in the United States it is reached about 6 months earlier in the corresponding socioeconomic group.

The adolescent spurt is at least partly under different hormonal control from growth in the preceding period (see Section V). Probably as a consequence of this the amount of height added during the spurt is to a considerable degree independent of the amount attained before it. Most children who have grown steadily up, say, the thirtieth percentile line on a height chart till adolescence, end up at the thirtieth percentile as adults, it is true, but a number end as high as the fiftieth or as low as the tenth, and a very few end at the fifty-fifth or fifth. The correlation between adult height and height just before the spurt starts is about 0.8. This leaves some 30% of the variability in adult height as due to differences in the magnitude of the adolescent spurt.

Practically all skeletal and muscular dimensions take part in the spurt, though not to an equal degree. Most of the spurt in height is due to acceleration of trunk length rather than length of legs. There is a fairly regular order in which the dimensions accelerate, leg length as a rule reaches its peak first, followed by the body breadths, with shoulder width last (Stolz and Stolz, 1951). Thus a boy stops growing out of his trousers (at least in length) a year before he stops growing out of his jackets. The earliest structures to reach their adult status are the head, hands, and feet. At adolescence, children, particularly girls, sometimes complain of having large hands and feet. They can be reassured that by the time they are fully grown their hands and feet will be a little smaller in proportion to their arms and

Fig 12 Mean velocity of combined muscle cross-sectional area (calf, arm, and thigh). Longitudinal data, individual curves aligned on peak height velocity (PHV). (From Tanner, 1965.)

legs, and considerably smaller in proportion to their trunk.

Changes in Body Composition at Adolescence

The relative changes in bone, muscle, and fat can be followed in radiographs of the limbs, taken in a standardized way (Tanner, 1964). The marked spurt in muscle is illustrated in Fig 12 and the simultaneous loss of fat in Fig 13. These curves are derived from 28 boys and 21 girls in the Harpenden Growth Study, measured each 6 months during puberty (for details see Tanner, 1965). The resulting individual curves have been aligned according to the child's point of peak height velocity (PHV) instead of according to chronological age. This technique, introduced into growth studies by Boas (see Tanner, 1959) some 80 years ago, and furthered by Shuttleworth (1937) and Stolz and Stolz (1951), overcomes the difficulty caused by some children having an early adolescent spurt and some a late one. When chronological age is used as a base, the mixture of preadolescent, midadolescent, and postadolescent children at each age obscures the course of events in the manner illustrated in Fig 3.

Figures 12 and 13 represent a summary of radiographic measurements of calf, thigh, and upper arm. In each case the widths of the bone, muscle, and fat were measured at a standard level, and the cross-sectional areas

Fig 13 Mean velocity of combined subcutaneous fat cross-sectional area (calf, arm, and thigh) Longitudinal data, individual curves aligned on peak height velocity (PHV) (From Tanner, 1965)

of each were calculated on the assumptions that the limb was circular, and that, at the level measured, the three tissues were distributed in concentric rings (Simple muscle and fat widths, however, give very similar curves) The values for muscle cross-sections in calf, arm, and thigh were summed, but with the thigh value halved first, since it was about twice that of the other regions The same procedure was followed with the fat

These figures give the velocity curves Both boys' and girls' muscle cross-sections (Fig 12) show large increases in velocity, reaching peaks a trifle after the points of maximal height velocity (when the boys' curve is smoothed) The boys reach a considerably greater velocity than the girls From infancy to adolescence boys have on average somewhat larger muscles than girls, but the girls' adolescent spurt, beginning two years earlier than the boys', carries them beyond the boys temporarily Thus from about 12½ to 13½ girls on average actually have larger muscles than boys Then the boys' spurt begins and the adult sex difference comes to be established

The curve for limb bone width resembles that for muscle, but with its peak coincident with peak height velocity The adolescent spurt is wholly or largely attributable to in-

crease in width of the dense bony cortex, the size of the marrow cavity on the inside of the bone seems to change little if at all (Tanner, 1968)

Figure 13 shows the curve for fat Boys on average actually lose fat at adolescence, with maximum rate of loss coincident with peak height velocity Girls show an identically shaped curve, but the decrease in velocity is not sufficiently great to carry the mean below zero, that is, to give an absolute loss Most girls have to content themselves with a temporary go-slow in fat accumulation Fat on the body shows a much smaller decrease of velocity than fat on the limbs (see Fig 7)

Strength and Exercise Tolerance

The increase in muscle size is naturally accompanied by an increase in strength, illustrated in Fig 14, drawn from the mixed longitudinal data of Jones (1949) Arm pull refers to the movement of pulling apart clasped hands held up in front of the chest, the hands each holding a dynamometer handle, arm thrust refers to the reverse movement of pushing the hands together Each individual test represents the best of three trials made in competition with a class mate of similar ability and against the individual's own figure of six months before Only with such precautions can maximal values be approached The boys show a very marked strength increase, whereas the girls have little real spurt, by the age of menarche their strength has reached its maximum Other data indicate that, except in hands and forearms, girls and boys are similar in strength for a given body size and shape until puberty begins

After adolescence, however, boys are much stronger, chiefly by virtue of having larger muscles, and partly, probably, by being able to develop more force per gram of muscle tissue They also develop larger hearts and lungs relative to their size, a higher systolic blood pressure, a lower resting heart rate, a greater capacity for carrying oxygen in the blood, and a greater power for neutralizing the chemical products of muscular exercise such as lactic acid (see Tanner, 1962, p 168) In short, the male becomes at adolescence more adapted for the tasks of hunting, fighting, and manipulating all sorts of heavy objects, as is necessary in some forms of food-gathering

Fig 14 Strength of arm pull and arm thrust from age 11 to 17 Mixed longitudinal data, 65–93 boys and 66–93 girls in each group (From Tanner, 1962, data from Jones, 1949)

The increase in hemoglobin, associated with a parallel increase in the number of red blood cells, is illustrated in Fig 15, drawn from the data of Young (1963). The hemoglobin concentration is plotted in relation to the development of secondary sex characters instead of chronological age, for the same reason as the muscle and fat cross-sections were previously plotted in relation to peak height velocity. Girls lack the rise in red cells and hemoglobin, which is brought about by the action of testosterone.

It is as a direct result of these anatomical and physiological changes that athletic ability increases so much in boys at adolescence. The popular notion of a boy "outgrowing his strength" at this time has little scientific support. It is true that the peak velocity of strength is reached a year or so later than that of height, so that a short period may exist when the adolescent, having completed his skeletal and probably also muscular growth, still does not have the strength of a young adult of the same body size and shape. But this is a temporary phase, considered absolutely, power, athletic skill, and physical endurance all increase progressively and rapidly throughout

adolescence. It is certainly not true that the changes accompanying adolescence enfeeble, even temporarily. If the adolescent becomes

Fig 16 Diagram of sequence of events at adolescence in boys. An average boy is represented, the range of ages within which each event charted may begin and end is given by the figures placed directly below its start and finish (From Tanner, 1962)

weak and easily exhausted it is for psychological reasons and not physiological ones

Development of the Reproductive System

The adolescent spurt in skeletal and muscular dimensions is closely related to the rapid development of the reproductive system which takes place at this time. In the older literature the word puberty was used to denote the appearance of the pubic hair, but more recently it has been taken to refer to the period of time at which the testes or ovaries and such organs as the uterus, prostate, and seminal vesicles suddenly enlarge. In this way it is possible to talk about puberty in mammals in general, for in most mammals the growth curves of these reproductive organs differ from the growth curves of other parts of the body by being nearly flat at first and then suddenly steeply rising (see Fig 6).

The sequence of events in man is shown diagrammatically in Figs 16 and 17. Figure 16 is largely based on the classic study by Herbert and Lois Stolz (1951) of the growth of 67 boys in Oakland, California, followed over seven years of adolescence. This study is remarkable both for the detail in which individual differences in growth rates were anal-

alyzed and for the introduction of carefully posed serial photographs as an integral part of the descriptive technique, a method later copied and made more quantifiable in the Harpenden Growth Study (Tanner, 1962). Figure 17 is chiefly based on Reynolds' and Wines' (1951) data from the Fels Research Institute, and also the data of Nicholson and Hanley (1953) and Tanner, Whitehouse, and Takaishi (1966). The solid areas in Fig 16 marked *penis* and *testis* represent the period of accelerated growth of these organs, and the horizontal lines and the rating numbers marked *pubic hair* stand for its advent and development. The sequence and timings given represent in each case an average value for West European boys, North Americans may average a few months earlier. To give an idea of the individual departures from the average, figures for the range of ages at which the spurts for height, penis growth, and testis growth begin and end are inserted under the first and last point of the curves or bars. The acceleration of penis growth, for example, begins on average at about age 13, but sometimes as early as 11 and sometimes as late as 14½. The completion of penis development usually occurs at about age 15 but in some

boys at 13½ and others at 17. There are a few boys, it will be noticed, who do not begin their spurts in height or penis development until the earliest maturers have entirely completed theirs. At ages 13 and 14 there is an enormous variability among any group of boys, who range all the way from practically complete maturity to absolute pre-adolescence. The psychological and social importance of this is discussed in the next section.

The *sequence* of events, though not exactly the same for each boy, is much less variable than the age at which the events occur. The first sign of puberty in the boy is usually an acceleration of the growth of the testes and scrotum. Slight growth of pubic hair may begin about the same time but is usually a trifle later. The spurts in height and penis growth begin about a year after the first testicular acceleration. The testicular growth is mainly due to increase in the size of the sperm-producing structures. The Leydig cells, which secrete male sex hormone, take up little space, they are present at birth but regress rapidly and from one month till puberty are few, inconspicuous, and inactive. At puberty they reappear and then full development, judged by histological criteria, is only reached late in puberty, at about the time when active sperm are being produced and the testes have reached near-adult size.

Some designation of how far a child has progressed through puberty is often required in clinical, educational, and anthropological work, and pictorial rating scales from 1 (pre-pubescent) to 5 for genital development in boys, breast development in girls, and pubic hair development in both sexes will be found in texts of adolescent development (e.g., Tanner, 1962, 1969). Some systems use a combination of genital and pubic hair growth for the male, but since some degree of dissociation between these two developments may occur, it is better to keep them separate. In this way also the same standards can be used for pubic hair in males and females. The size of the testes can be approximately determined by comparison with a string of standard plastic models of the same shape as the testis, known as the Prader orchidometer.

Axillary and facial hair both appear on average some two years after the beginning of pubic hair growth. There is a definite order in which the hairs of mustache and beard

appear, first at the corners of the upper lip, and then over the whole upper lip, then the upper part of the cheeks and the midline below the lower lip, and finally along the sides and lower border of the chin. The remainder of the body hair appears from about the time of first axillary hair development until a considerable time after puberty. The ultimate amount of body hair an individual develops seems to depend largely on heredity, though whether because of the kinds and amounts of hormones secreted or because of the reactivity of the end-organs is not known.

Breaking of the voice occurs relatively late in adolescence, it is often a gradual process and so not suitable as a criterion of puberty. It accompanies enlargement of the larynx, caused by the action of testosterone on the laryngeal cartilages.

During adolescence the male breast undergoes changes, some temporary and some permanent. The diameter of the areola, which is equal in both sexes before puberty, increases considerably, although less than it does in girls. Representative figures are 12.5 mm before puberty, 21.5 mm in mature men, and 35.5 mm in mature women (Carn, 1952). In some boys (between a fifth and a third of most groups studied) there is a distinct enlargement of the breast about midway through adolescence. This usually regresses again after about one year.

Concomitantly with growth of the penis, and under the same influence, the prostate gland and seminal vesicles enlarge. The time of the first ejaculation of seminal fluid is to some extent culturally as well as biologically determined, but as a rule it is during adolescence and about a year after the beginning of accelerated penis growth.

The sequence of events in girls is shown in Fig. 17. The appearance of the "breast bud" (stage 2 in breast development) is as a rule the first sign of puberty in girls, though the appearance of pubic hair sometimes precedes it. The uterus and vagina develop simultaneously with the breast. As in boys, there is a large variation in the age at which the various events occur. Menarche, the first menstrual period, is a late event in the sequence. It occurs almost invariably after the peak of the height spurt has been passed.

In Fig. 18 a Gompertz curve has been fitted to the height measurements of a girl

Fig 17 Diagram of sequence of events at adolescence in girls. An average girl is represented, the range of ages within which some of the events may occur is given by the figures placed directly below them (From Tanner, 1962)

from 10½ to 16, and differentiated to give the smoothed velocity (middle) and acceleration (lower) curves. The acceleration begins by rising to a peak, then falls progressively, crosses the zero line at the point of maximal velocity, reaches its own maximum deceleration, and then returns to zero. B2 represents the first appearance of breast bud and B5 the time at which a more or less adult breast form was reached. The first appearance of pubic hair could not be determined since only photographs were available, but P3 and P5 give the intermediate and completed pubic hair points. Menarche is also given. This particular girl's menarche took place some seven months later than average, but its relationship with the height curve is typical. Menarche occurred at the moment when deceleration was maximal, as is usually the case. This relationship makes the point that some hormonal forces may be better reflected in acceleration rather than velocity or distance curves.

Menarche marks a definitive and probably mature stage of uterine development, but it does not usually signify the attainment of full reproductive function. The early menstrual

cycles, which in some girls are more irregular than later ones, often occur without an ovum being shed. There is frequently a period of adolescent sterility, lasting a year or 18 months after menarche. The same occurs in apes and monkeys. Similar considerations may apply to the male, but there is no reliable information on this. On average girls grow about 6 cm more after menarche, although gains of up to twice this amount may occur. The gain is practically independent of whether menarche occurs early or late.

The diagrams of Figs 16, 17, and 18 must not be allowed to obscure the fact that children vary a good deal in the relative closeness with which the various events of puberty are linked together. At one extreme we may find a girl who has not yet menstruated, though she has reached adult breast and pubic hair ratings and is already two years past her peak height velocity, at the other we may find a girl who has passed all the stages of puberty within the space of two years. In Fig 19 the relations between events in a series of girls in the Harpenden Growth Study are charted (Marshall and Tanner, unpublished). The variability between in-

Fig 18 Height attained, height velocity, and height acceleration curves of a girl at adolescence B2 marks beginning of breast development, B5 adult form P3 marks intermediate stage of pubic hair development, P5 adult form M marks menarche (From Tanner, 1967)

dividuals is equally marked in boys The average boy takes about two years to pass from genital stage 2 to stage 4, but exceptional boys may take as long as five years In both sexes the acceleration in skeletal development and the development of genitalia and breasts are rather closely linked The growth of pubic hair is a little less closely bound up with skeletal and reproductive events (see Reynolds and Wines, 1951)

The basis for some children having loose and some tight linkages between pubertal events is not known Probably the linkage reflects the degree of integration of various processes in the hypothalamus and the pituitary gland, for breast growth is controlled by one group of hormones, pubic hair growth

by another, and the height spurt probably by a third (see Section V)

The Development of Sex Dimorphism

The differential effects on the growth of bone, muscle, and fat at puberty increase considerably the difference in body composition between the sexes Boys have a greater increase not only in the length of bones but in the thickness of cortex, and girls have a smaller loss of fat Thus it is usually possible to tell an adult man from an adult woman by examining merely a radiograph of the calf A discriminant function using fat and bone widths separates the sexes after puberty with only 5% misclassified But before puberty we can do barely better than chance (Tanner, 1962)

There are, of course, a number of better-known sexual dimorphisms in man Among the differences in body size and shape the most striking ones are the man's greater stature and breadth of shoulders and the woman's wider hips These dimorphisms are produced chiefly by the changes and timing of puberty Boys and girls are almost the same height before puberty, but boys have a greater adolescent height spurt Furthermore, they have two more years of pre-adolescent growth than girls, thus when their spurt

Fig 19 Intervals between different events of puberty in a series of 29 girls Girls are aligned by peak height velocity (From Marshall and Tanner, unpub)

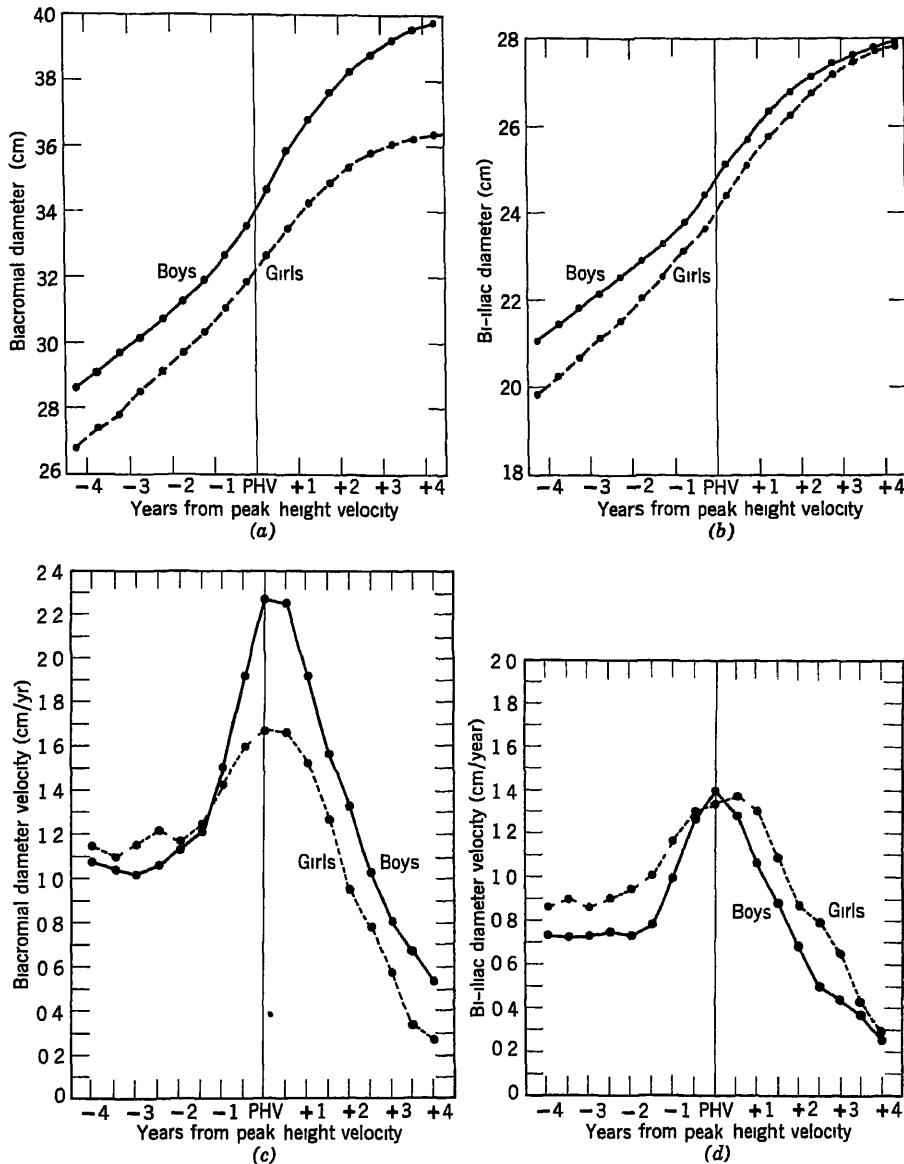

Fig 20 Distance (a and b) and velocity (c and d) curves of shoulder width and hip breadth in boys and girls at puberty, plotted against peak height velocity "age" Mixed longitudinal data of Harpenden Growth Study

starts they are on average about 10 cm taller than were the girls when their spurt began. This difference in tempo of growth, as Boas called it, is also to a large extent responsible for men's legs being longer than women's relative to their body length. During the immediately pre-adolescent years the legs are growing relatively faster than the trunk, and boys spend longer in this phase of growth.

The manner in which the shoulder/hip distinction arises is illustrated in Fig 20. Girls have a particularly large adolescent spurt in hip width, a spurt which is quantitatively as great as that of the boys' despite the girls' spurt being in most other dimensions a good deal less. The shoulder width spurt, on the other hand, is particularly marked in boys. These differences in growth

occur because cartilage cells in the hip joint area of the pelvis are specialized to multiply in response to estrogens, and cartilage cells in the shoulder region are specialized to respond to androgens such as testosterone. Such specializations can be lost as well as gained during the course of evolution. In most apes and monkeys the male has a large canine tooth, suitable for fighting. This normally develops at puberty, but it can be induced to grow before then by administration of testosterone. In man the canine, though slightly bigger in the male, has apparently lost most of its ability to respond to androgens.

The shoulder-hip width dimorphism has long been used as a measure of bodily androgyny, that is, of the degree to which a male resembles a female and vice versa. A discriminant function using just these two measurements misclassifies about 10% of young adults. It has the form $3 \text{ Biacromial diam} - 1 \text{ Bi-iliac diam}$ and this may be used as an androgyny score which is less biased by sheer body size than the simple ratio of shoulder to hip widths. The trunk-leg difference can be taken into account also, leading to only 6% misclassification, by using the score $3 \text{ Biacromial diam} - 1 \text{ Bi-iliac diam} + 0.5 \text{ Subischial length}$ (subischial length is stature less sitting height) (Tanner, 1951, 1962). These scores can be used in children as well as adults, but without any guarantee that the weights are appropriate for best separating pubescent boys and pubescent girls. Before puberty little discrimination is possible, separation increases as puberty progresses.

It is important to remember that sex dimorphisms do not only arise at puberty. Many dimorphisms appear much earlier. Some, like the external genital difference itself, develop during fetal life. Others develop continuously throughout the whole growth period by a sustained differential growth rate rather than a differential growth rate operating only at a particular time such as puberty. An example of this is the greater relative length and breadth of the forearm in the male when compared with whole arm length or whole body length (see Tanner, 1962, Hiernaux, 1968 for further discussion). A major dimorphism, and one which leads to others, is the difference in rate of maturing, discussed in the next section.

Part of the sex difference in pelvis shape antedates puberty. Girls at birth already have a wider pelvic outlet, that is, a wider opening at the bottom of the bony pelvis, which constitutes the narrowest part of the canal through which a baby has to pass when it is born. Thus the adaptation for child-bearing is present from a very early age. The changes at puberty are concerned more with widening the pelvic inlet and broadening the much more noticeable hips. It seems likely that these changes are more important in attracting the males' attention than in dealing with its ultimate product.

For these sex-differentiated morphological characters arising at puberty—to which we can add the corresponding physiological and perhaps psychological ones as well—are secondary sex characters in the straightforward sense that they are caused by sex hormone or sex-differential hormone secretion and serve reproductive activity directly. Some serve more directly than others, naturally. The penis is directly concerned in copulation, the mammary gland in lactation. The wide shoulders and muscular power of the male may perhaps also have been developed for use in copulation, or more probably, together with the canine teeth and brow ridges in man's ancestors, they developed for driving away other males and insuring peace from other animals, an adaptation which soon becomes social. The dimorphism is originally maintained by sexual selection, since the fighting involves males of the same species. When this type of sexual selection becomes less important, as in man, genetical theory leads us to suppose that these traits are gradually eliminated.

But a number of traits persist, perhaps through another mechanism known to the ethologists as ritualization. In the course of evolution a morphological character or a piece of behavior may lose its original function and, becoming further elaborated, complicated, or simplified, may serve as a sign stimulus to other members of the same species, releasing behavior that is in some way advantageous to the spread or survival of the species. It requires little insight into human erotics to suppose that the shoulders, the hips and buttocks, and the breasts (at least in a number of widespread cultures) serve as releasers of mating behavior. The pubic

han (about whose function the medical textbooks have always preserved a cautious silence) probably survives as a ritualized stimulus for sexual activity, developed by simplification from the han remaining in the inguinal and axillary regions for the infant to cling to when still transported, as in present apes and monkeys, under the mother's body. Similar considerations may apply to axillary han, which is associated with special apocrine glands which themselves only develop at puberty and are related histologically to scent glands in other mammals. The beard, on the other hand, may still be more frightening to other males than enticing to females.

At least ritual use in past communities suggests this is the case, but perhaps there are two sorts of beards.

IV DEVELOPMENTAL AGE EARLY AND LATE MATURERS

Children vary greatly in the rate at which they develop, in their tempo of growth. The effects are most dramatically seen at adolescence. In Fig 21 are three boys all aged exactly 14.75 years and three girls all aged exactly 12.75. All are entirely normal and healthy. At ages 13, 14, and 15 in boys and 11, 12, 13 in girls there is an enormous range

Fig 21 Differing degrees of pubertal development at the same chronological age. Upper row three boys all aged 14.75 years. Lower row three girls all aged 12.75 years. (From Tanner, 1969.)

of development, running all the way from complete maturity to absolute pre-adolescence. The boy on the left in the figure is small, with childish muscles and no development of reproductive organs or pubic hair, the boy on the right is practically a grown man, with broad shoulders, strong muscles, adult genitalia, and a bass voice, he could easily be mistaken for a 17- or 18-year-old.

Manifestly it is ridiculous to consider all these three boys as equally grown up either physically, or, since much behavior at this age is conditioned by physical status, in their social relations. The statement that a boy is 14 is in most contexts hopelessly vague, all depends, morphologically, physiologically, and to a considerable extent sociologically too, on whether he is pre-adolescent, midadolescent or postadolescent.

Evidently some designation of physical maturity, apart from chronological age, is needed, and in this instance the obvious one would be the degree of development of the reproductive system. But the same individual differences in tempo of growth occur at all ages, even if not so obviously as at adolescence. Thus we need a measure of *developmental age* or *physiological maturity* applicable throughout the whole period of growth. There are numerous possible measures that meet this criterion in whole or in part, ranging from the number of erupted teeth to the percentage of water in muscle cells. The various developmental "age" scales do not necessarily coincide, and each has its particular use. By far the most generally useful, however, is skeletal maturity or *bone age*. Others of potentially general concern are dental maturity and shape age.

Skeletal Maturity

Skeletal maturity is a measure of how far the bones of an area have progressed toward maturity, not in size, but in shape and in their relative positions one to another, as seen in a radiograph. Each bone begins as a primary center of ossification, passes through various stages of enlargement and shaping of the ossified area, acquires in some cases one or more epiphyses, that is, other centers where ossification begins independently of the main center, and finally reaches adult form when these epiphyses fuse with the main body of the bone. All these changes can be

easily seen in a radiograph, which distinguishes the ossified area, whose calcium content renders it opaque to the X-rays, from the areas of cartilage where ossification has not yet begun. The *sequence* of changes of shape through which each of the bone centers and epiphyses pass is the same in all individuals. Skeletal maturity is judged both from the number of centers present and the stage of development of each.

In principle any or all parts of the skeleton could be used to give an assessment of skeletal maturity, but in practice the hand and wrist form the most convenient area and the one generally used. The hand is an area where a large number of bones and epiphyses develop, and an X-ray of it is easily made without exposing the remainder of the body to measurable doses of radiation. It itself requires only a very small dose of X-rays (Garn, Helmrich, Flaherty, and Silverman, 1967). This is of the order of 4 milliroentgens, a figure which should be compared with the amount received from unavoidable everyday background radiation, which is 100 milliroentgens per year at sea level rising to 300 milliroentgens at 2000 meters. There is no evidence that 4 milliroentgens does any harm whatever, indeed it would be surprising if it did, since it represents the dose obtained unavoidably by every child who spends a week on holiday in the mountains. We emphasize this now because the public is justifiably worried about the medical and genetic effects of atomic fallout and about the doses of radiation given in diagnostic radiology and, to a far greater degree, in radiotherapy in hospitals. The matter can only be put in perspective by thinking in quantitative terms, even simple diagnostic procedures in hospitals may involve a hundred times the dose of a bone-age radiograph, and radiotherapy procedures run up to a million times the dose.

For the radiograph the left hand is used, placed flat on an X-ray cassette with the palm down and the tube positioned 30 inches above the knuckle of the middle finger. The skeletal maturity assessment is made by comparing the given radiograph with a set of standards. There are two ways in which this may be done. In the older, "atlas" method, the radiograph is matched successively with the standard Greulich-Pyle (1959) plates

representing ages 5.0, 6.0, and so on. The age of the standard with which the radiograph most nearly coincides is recorded as the skeletal "age," interpolation between standards being made if it is thought to be justifiable. In the more recently developed "maturity points" method (see Acheson, 1966) a series of standard stages are given for each individual bone, independent of age, and each bone of the radiograph is assigned a score corresponding to the stage it has reached. The scores are mathematically weighted to produce the best overall estimate of total maturity. The scores for the individual bones are added, thus the whole hand radiograph scores a total of so many weighted maturity points. This score is then compared with the range of scores of a standard group at the same age and a percentile status is assigned, just as it would be for height. A skeletal age may also be assigned, this being simply the age at which the given score lies at the fiftieth percentile. This method is somewhat finer in gradation and easier to use than the atlas method, although it is slightly more time-consuming. The standards are those of Tanner, Whitehouse, and Healy (1962), and it must be remembered that they are based on a large random sample of Scottish urban and rural children, who are six to nine months less advanced than the North American well-off middle-class children on whom the Greulich-Pyle method was standardized. Thus the two methods do not lead to the same result in terms of bone age, unless a correction is made.

In the Greulich-Pyle standard boys and girls have a different series of plates, since the girls are more advanced. The Tanner-Whitehouse stages for each individual bone are common to both sexes, and the sequence of appearance and development of one bone relative to another in the hand is also closely similar. Hence in this method only one set of standards is used. The skeletal maturity score at any given chronological age is simply higher for girls than for boys. This is illustrated in Fig. 22, which shows the standard percentile chart for boys, with the fiftieth percentile line for girls of the same chronological age plotted upon it. The early- and late-maturing boys seen in Fig. 21 are also shown. It is noteworthy that this measure of skeletal maturity has a marked adolescent

spurt. There is evidence that the hormonal control of skeletal maturation is different before and during the spurt. The maturity score can itself be used as a scale of developmental age common to boys and girls, against which hormone excretions and other functions may be plotted (Tanner, 1969).

Skeletal maturity provides a true common scale of development, which measures such as "height age," sometimes used by paediatricians, and indeed IQ fails to do. This is because every healthy individual reaches the same skeletal maturity eventually. The skeletal score represents a "per cent of maturity attained", thus a low score for age can be unequivocally taken to signify retardation in the true sense of delay in skeletal maturing. Final adult height or final IQ, on the other hand, varies from individual to individual. For this reason height age and mental age are more closely related to final height and final IQ than to advancement/retardation. Hence height ages cannot be validly compared from one individual to another as a measure of maturity status.

Standards are available for skeletal development of the pelvis and knee and ankle, besides the hand and wrist. Indeed, at ages under 1 year the knee and ankle provide better estimates of maturity than the hand, and in work upon infants and newborns the stages described by Vincent and Hugon (1962) should be used with locally derived norms.

Dental Maturity

Dental maturity can be obtained by counting the number of teeth erupted and relating this to standard figures in much the same way as skeletal maturity. The deciduous dentition erupts from about 6 months to 2 years of age and can be used during this period. The permanent or second dentition provides a measure from about 6 to 13 years. From 2 to 6 and from 13 on little information is obtainable from the teeth by simple counting, but stages of calcification of teeth as seen in jaw radiographs can be used in just the same way as calcification in the bones of the hand and wrist.

Shape Age

As the child grows older his shape changes because different parts of the body grow at

Fig 22 Tanner-Whitehouse skeletal maturity standards for boys Heavy dashed line shows the fiftieth percentile for girls The dots show skeletal maturity scores from $13\frac{1}{2}$ onwards of the early- and late-maturing boys represented in Fig 21 at age 14.75 The larger dots represent the age illustrated in Fig. 21

different rates The legs and arms get relatively longer and the head relatively smaller, for example In a culture where birth date is unknown a remarkably crude but reputedly

effective way of judging whether a child is old enough to work, attend school, or carry out some other task is to see if he can touch his left ear with his right hand, the arm pass-

Fig 23 Relation of skeletal maturity and age at menarche. Skeletal development ages (Todd Standards) for early-, average-, and late-menarche groups of girls, from age 7 to maturity. ing over the top of the head. In Europe it was formerly (and is sometimes actually) proposed that children should begin to attend school only when a certain "form-change" (*gestaltwandel*) has occurred and should only go on from one type of school to another at a second "form-change" (Zeller, 1952).

In principle the degree of shape change achieved could be made a measure, and a very convenient one, of developmental maturity. But it would only be useful if a measure could be devised which is independent of the final shape reached. Otherwise it would be subject to the same criticism as height age. To find such a measure is a mathematically complex and difficult task, not yet accomplished.

Relations between Different Measures of Maturity

Skeletal maturity is closely related to the age at which adolescence occurs, that is, to maturity measured by secondary sex character development. Thus the range of chronological age within which menarche may normally fall is about 10 to 16½, but the corresponding

range of skeletal age is only 12 to 14½. Evidently the physiological processes controlling progression of skeletal development are in most instances closely linked with those that initiate the events of adolescence. This is illustrated in Fig 23. Three groups of girls are plotted, those with an early, those with a middling, and those with a late menarche. The points M1, M2, and M3 represent the average age of menarche in each group. Those with an early menarche have an advanced skeletal age, those with a late menarche a retarded skeletal age. The linkage, however, is not complete, menarche occurs at a slightly greater skeletal age in the successive groups, not at precisely the same one.

Figure 23 illustrates another important point. Children tend to be consistently advanced or retarded in maturity during their whole growth period, or at any rate after about age 3. The early-menarche girls are skeletally advanced not only at the age at which menarche takes place, but at all ages back to 7. The late-menarche group is consistently retarded. The correlation between menarcheal age and skeletal age at menarche itself is about .85, and between menarcheal age and skeletal age at chronological age 5 or 6 is about .55. The correlation becomes less the further back in growth one goes. The children's velocity curves are steeper then and they cross each other more, bringing reassortment of growth status, and the same is true of their skeletal maturity curves. By and large, however, there is a consistency in acceleration or retardation of skeletal and general bodily maturity.

Dental maturity partly shares in this general skeletal and bodily maturation. At all ages from 6 to 13 children who are advanced skeletally have on average more erupted teeth than those who are skeletally retarded. Likewise those who have an early adolescence on average erupt their teeth early, as shown in Fig 24 (see also Garn, Lewis and Kerewsky, 1965a). Girls on average have more erupted teeth than boys of the same age.

But this relationship is not a very close one, as the figure also implies, even with only three maturity groups in each sex some crossing of the lines takes place. Quantitatively it is the relative independence of teeth and general skeletal development which should be emphasized. This is not surprising, in that the teeth are part of the head of the organism, and as

Fig 24 Total number of erupted teeth at each age for early-, medium-, and late-maturing girls and boys. Maturity groups defined by age at peak height velocity. Mixed longitudinal data, reported longitudinally (From Tanner, 1962, redrawn from Shuttleworth, 1939)

we have already seen, the head is advanced over the rest of the body and for this reason its growth curve and growth control differ somewhat from the general growth curve.

Evidently there is some general factor of bodily maturity throughout growth, creating a tendency for a child to be advanced or retarded as a whole, in his skeletal ossification, in the percentage attained of his eventual size, in his permanent dentition, doubtless in his physiological reactions, and possibly in his intelligence test results also. But not too much should be made of this general factor. It should be especially noted how very limited

is the loading, so to speak, of brain growth in it. There is little justification in the facts of physical growth and development for the concept of "organismic age" in which almost wholly disparate measures of developmental maturity are lumped together.

Set under this general tendency are groups of more limited maturities, which vary independently of it and of each other. The teeth constitute two of these limited areas (primary and secondary dentition being largely independent of each other), the ossification centers another, the brain at least one more. Some of the mechanisms behind these relations can

be dimly seen. In children who lack adequate thyroid gland secretion, for example, tooth eruption, skeletal development, and brain organization are all retarded, whereas in children with precocious puberty, whether due to a brain disorder or a disease of the adrenal gland, there is advancement of skeletal and genital maturity without any corresponding effect upon the teeth or, as far as we can tell, upon the progression of organization of the brain.

Sex Differences in Developmental Age

Girls are on average ahead of boys in skeletal maturity from birth till adulthood, and in dental maturity also during the whole of the permanent dentition eruption (though not, curiously, in primary dentition). It would seem therefore that the sex difference lies in the general maturity factor (as well as in various more detailed factors). Girls are usually ahead of boys in motor development also and in certain forms of aptitude tests.

The skeletal age difference begins during fetal life, the male retardation being due, probably indirectly, to the action of genes on the Y chromosome. Children with the abnormal chromosome constitution XXY (Klinefelter's syndrome) have a skeletal maturity indistinguishable from the normal XY male, and children with the chromosome constitution XO (Turner's syndrome) have skeletal maturities approximating to the normal female XX, at least until puberty. The male retardation may be established as early as the differentiation of testis or ovary, or, more probably, it may be caused by the secretion by the fetal gonads or adrenals of sex-specific hormones. At birth boys are about four weeks behind girls in skeletal age, and from then till adulthood they remain about 80% of the skeletal age of girls of the same chronological age. The percentage difference in dental age is not so great, boys being about 95% of the dental age of girls.

The sex difference is not precisely the same for all bones, nor for all teeth. There is a sex-bone and sex-tooth interaction. Thus in girls the canines erupt on average 11 months earlier than in boys, whereas the first molars erupt only two months earlier. Similar effects are seen in skeletal ossification, particularly in knee and elbow (Garn, Rohmann, and Blumenthal, 1966).

The sex difference in skeletal maturity is not confined to man but occurs in chimpanzees, gorillas, and rhesus monkeys, and in rats also. It may be characteristic of all or most mammals. Its full biological significance is not at present obvious.

Developmental Age and the Prediction of Adult Height

The age at which growth ceases is related much more closely to the age at which adolescence occurs than to chronological age. After the age of 9 the amount of growth left to occur, and hence final adult stature, can be predicted better by reference to skeletal age than to chronological age. This can sometimes be of practical educational or social importance. For example, girls usually enter the Royal Ballet School at 9 or 10 years old, and thereafter they undergo a very rigorous and specialized training and are vocationally oriented to becoming dancers. But the exigencies of the *corps de ballet* require that the dancers shall all be within certain rather narrow height limits. If a girl grows up to be too short or too tall her career may be over. We cannot as yet control the extent to which children grow—and perhaps we should not when we can—but we can at least warn on entry those whose chances of ending between the required height limits are statistically rather small. The prediction of adult height requires knowledge of chronological age, bone age, and present height. We use either the Greulich-Pyle atlas for bone age and then the Bayley-Pinneau (1952) tables, or the Tanner-Whitehouse skeletal maturity and an associated multiple regression equation. The accuracy is such that 90% of predictions from age 9 on lie within $\pm 1\frac{1}{2}$ inches of true final height. This is rather better than predictions based on height of parents.

Physical Maturation, Mental Ability, and Emotional Development

Clearly the occurrence of tempo differences in human growth may have profound implications for educational theory and practice. This would especially be so if advancement in physical growth were linked to any significant degree with advancement in intellectual ability and in emotional maturity.

There is good evidence that in the European and North American school systems

children, who are physically advanced toward maturity, score on average slightly higher in most tests of mental ability than children of the same age who are physically less mature. The difference is not great, but it is consistent and it occurs at all ages that have been studied, going back as far as 6½ years. Similarly, the intelligence test score of postmenarcheal girls is higher than the score of premenarcheal girls of the same age (see references in Tanner, 1962, 1966c). Thus in age-linked examinations physically fast-maturing children have a significantly better chance than slow-maturing children.

It is also true that physically large children score higher than small ones, at all ages from 6 on. In a random sample of all Scottish 11-year-old children, comprising 6940 pupils, the correlation between height and score in the Moiray House group test was 25 ± 01 , allowing for the effect of age difference from 11.0 to 11.9 (Scottish Council, 1953). An approximate conversion of these test scores to Terman-Merrill IQ leads to an average increase of .67 points for each centimeter of stature, or roughly 1½ points per inch. A similar correlation was found in London children. The effects can be very significant for individual children. In 10-year-old girls there was a 9-point difference in IQ between those whose height was above the seventy-fifth percentile and those whose height was below the fifteenth. This is two-thirds of the standard deviation of the test score.

Children with many sibs are shorter in stature and score less in intelligence tests than children with few sibs. About half of the correlation above is associated with differences in sib number, but about half remains when number of sibs is allowed for (Scott, 1962).

It was usually thought that both the relationships between test score and height and between test score and early maturing would disappear in adulthood. If the correlations represented only the effects of co-advancement both of mental ability and physical growth, this might be expected to happen. There is indeed no difference in height between early- and late-maturing boys when both have finished growing. But it is now clear that, curiously, at least part of the height-IQ correlation persists in adults (Tanner, 1966c). It is not clear in what proportion genetical and enviro-

mental factors are responsible for this (see Section VIII).

There is little doubt that being an early or a late maturer may have repercussions on behavior, and that in some children these repercussions may be considerable. There is little enough solid information on the relation between emotional and physiological development, but what there is supports the common-sense notion that emotional attitudes are clearly related to physiological events.

The world of the small boy is one where physical prowess brings prestige as well as success, where the body is very much an instrument of the person. Boys who are advanced in development, not only at puberty but before as well, are more likely than others to be leaders. Indeed this is reinforced by the fact that muscular, powerful boys on average mature earlier than others and have an early adolescent growth-spurt. The athletically built boy not only tends to dominate his fellows before puberty, but by getting an early start he is in a good position to continue that domination. The unathletic, lanky boy, unable, perhaps, to hold his own in the pre-adolescent rough and tumble, gets still further pushed to the wall at adolescence, as he sees others shoot up while he remains nearly stationary in growth. Even boys several years younger now suddenly surpass him in size and athletic skill, and perhaps, too, in social graces. Figure 25 shows the height curves of two boys, the first an early-maturing, muscular boy, the other a late-maturing, lanky one. Although both boys are of average height at age 11, and are together again at average height at age 17, the early maturer is 4 inches taller during the peak of adolescence.

The late developer at adolescence may sometimes have doubts about whether he will ever develop his body properly and whether he will be as well endowed sexually as those others he has seen developing around him. At a deeper level the lack of development may act as a trigger to reverberate fears accumulated deeper in the mind during the early years of life.

It may seem as though early maturers have things all their own way. But early maturers have their difficulties also, and particularly the girls in some societies. Though some gloat in their new possessions, others are embarrassed by them. The early maturer has a longer

Fig 25 Height attained from age 11 to 17 of two boys of Harpenden Growth Study, one (M613) with an early and the other (M112) with a later adolescent spurt. The plots are made against the Tanner-Whitehouse 1965 British Standards (Redrawn from Tanner, 1961)

period of frustration of sex drive and of drive toward independence and the establishment of vocational orientation. Studies at the University of California have given evidence of the psychological consequence of early and late maturing. Late-maturing boys showed more attention-getting behavior and were rated by their age peers and trained observers as more restless, talkative, and bossy. They were less popular and had lower social status. In contrast, the outstanding leaders came from the early-maturing group. Projective techniques revealed in the late maturers deeper feelings of inadequacy, greater anxiety, and

greater anticipation of rejection by the group. Follow-up studies in young adulthood showed that, at least in the society of the United States, the early-maturing boys became more sociable and less neurotic (Jones, 1957, Mussen and Jones, 1957 and 1958).

Little can be done to diminish the individual differences in children's tempo of growth, for they are biologically rooted and not significantly reducible by any social steps we may take. It therefore behooves all teachers, psychologists, and pediatricians to be fully aware of the facts and alert to the individual problems they raise.

V ENDOCRINOLOGY OF GROWTH

The endocrine glands, of great importance in the control of growth and development, are one of the chief agents for translating the instructions of the genes into the reality of the adult form, at the pace and with the result permitted by the available environment.

The hormones particularly concerned in growth are thyroxine from the thyroid gland, cortisol and adrenal androgens from the cortex of the adrenal gland, testosterone from the Leydig cells of the testes, estrogens from the ovary, insulin from the islets of Langerhans in the pancreas and growth hormone from the pituitary gland. The pituitary in addition produces thyroid-stimulating hormone (TSH), adrenocorticotrophic hormone (ACTH), and at least two gonadotrophic hormones. These are follicle-stimulating hormone (FSH), which stimulates growth of the follicles in the ovary or the sperm-producing cells in the testis, and luteinizing hormone (LH), also called interstitial-cell-stimulating hormone (ICSH), which stimulates the growth and secretion of the corpus luteum in the ovary or the Leydig (also called interstitial) cells in the testis. Another gonadotrophic hormone, with actions similar to but not identical with either FSH or LH, is produced by the cells of the chorion, which is the layer of the placenta nearest the maternal circulation. Chorionic gonadotrophin, as it is called, therefore enters primarily the maternal circulation. Lactogenic hormone, produced by the pituitary and necessary for lactation (also called prolactin) is very similar to growth hormone. Some animals have also a pituitary mammogenic hormone, essential for development of the mammary glands.

Control of Endocrine Secretions

Most endocrine glands secrete their hormones in response to the stimulus of an activating hormone from the pituitary gland. Thus thyroxine is secreted in response to pituitary thyroid-stimulating hormone, cortisol in response to adrenocorticotrophic hormone, and so on. The pituitary hormones are themselves secreted in response to the arrival of releaser substances originating in nearby areas of the brain, chiefly the median eminence of the hypothalamus. The releaser substances, in turn,

are secreted or switched off in response to certain defined stimuli, in some cases a drop or rise in the level of the hormone in the blood, sensed by specialized cells also in the hypothalamus, near to the cells which synthesize and secrete the releasers. Thus a feedback circuit is established: sensor—releaser—pituitary hormone—"peripheral" hormone—sensor. Outside influences can play on the circuit, particularly at the junctions: peripheral hormone—sensor, and sensor—releaser. Thus nervous impulses from other parts of the brain may alter the threshold of the sensor. The way puberty is believed to be initiated provides an example. Before puberty the sensor for estrogen is set so it responds by discontinuing the release of FSH when blood estrogen is still at a very low level. Then impulses arrive which diminish the sensitivity of the sensor so that now it only responds to a high level of estrogen. In consequence FSH is not switched off, blood estrogen rises, and development of the breasts and uterus occurs. Influences from outside the organism affect endocrine function as a rule by this type of action. It is believed, for example, that severe psychological stress may cause dwarfism in certain children by switching off their secretion of growth hormone. This may be either by affecting the sensor or by raising the threshold at which the neural growth hormone releaser is secreted.

There may be a number of sensors all acting on one releaser and they may change their relative importance at different times of life or under different circumstances. Thus there is probably one sensor for growth hormone releaser which responds to a drop in blood sugar and another which responds to a rise in certain amino acids, one may be more important in fetal life and another in childhood. Certainly there are many sensors of which we are still ignorant, and probably there are some releasers and even some pituitary hormones (e.g., the stimulus to adrenal androgen secretion at puberty) that are still unknown.

Some hormones are released usually or sometimes without the full circuit being involved. There is good evidence that a rise in the level of blood thyroxine is sensed usually directly at the pituitary level, switching off the secretion of TSH immediately, rather than at the level of the hypothalamus.

Prenatal Period

Most of the endocrine glands begin to function relatively early in fetal life and are clearly of importance in the healthy development of the fetus. However, the immense technical difficulty of investigating endocrine function at this time of life has so far precluded much detailed knowledge of the situation in the human. For several hormones we do not even know to what extent the fetus, at various ages, has itself to secrete the compound and to what extent it can rely on transfer across the placenta of the hormone secreted by the mother.

We have very little knowledge about the maturation of the hypothalamus-pituitary feedback system in the fetus. For one thing, we are grossly ignorant of the development of the human hypothalamus in terms of histochemistry, ultrastructure, and even conventional cytology. Neurosecretory material, presumed to be releasing substances, is first seen at about 20 weeks postmenstrual age in the nerve cells near the capillary loops of the hypophyseal-portal system of blood vessels which carry the releases from brain to pituitary. Thus it appears that this part of the system starts to function about halfway through pregnancy (Raiha and Hjelt, 1957). Various hormones are present in the pituitary gland before this, but we cannot take their presence to imply they are secreted, only that they are synthesized.

Thyroid hormone (thyroxine) is necessary for the normal development of the brain. It begins to be secreted by the fetal pituitary around the fifteenth to twentieth postmenstrual week, probably under the stimulus of TSH from the fetal pituitary. Maternal TSH does not cross the placenta, and maternal thyroid hormone does so only in insignificantly small amounts (Fiench and van Wyke, 1964). Thyroid hormone affects protein synthesis in the brain of the fetus and the very young child. As the brain matures this action diminishes. In the absence of adequate thyroid hormone, the nerve cell bodies and their dendrites and axons are all reduced in size, the dendrites branch less and the connectivity (see Section VI) is decreased (Eayrs, 1964). These changes are irreversible if they persist for very long.

The adrenal gland in the human fetus consists of the inner medulla and the function-

ally and structurally quite different outer cortex, as in the adult. But the cortex in the fetus differs in appearance, and presumably in function, from the adult cortex. There is a special fetal zone of cells, constituting 80% of the cortex, lying between the medulla and the outer 20% of cells, which resemble the adult tissue. This "fetal cortex" grows steadily from about 12 postmenstrual weeks till birth or a little before, when it atrophies rapidly, the weight of the two adrenals falling from around 6 gm at birth to around 3 gm a month later. There is no appreciable sex difference. The fetal cortex is not incorporated into the permanent cortex, which develops separately, for the most part after the fetal cortex has disappeared. The fetal cortex is characteristic of primates, it seems, though a somewhat analogous zone arises about 2 weeks after birth in mice. It is not yet clear whether ACTH from the fetal pituitary is the factor responsible for its growth in man or whether chorionic gonadotrophin is the stimulus (Lauitzen and Lehmann, 1967). Nor is it clear what causes it to secrete whatever it does secrete. Fetal ACTH secretion is itself probably caused by the secretion of corticotrophin-releasing factor (CRF) by the hypothalamus (see Jost, 1966).

In the adult the adrenal cortex secretes mainly three groups of hormones

1 Mineralocorticoids Aldosterone and to a lesser extent 11-deoxy-corticosterone, which maintain within acceptable limits the concentrations of sodium and potassium in the tissue fluids, are thus essential to life. The secretion is not controlled by a pituitary hormone but directly by alterations in blood volume and composition.

2 Glucocorticoids (or Corticoids) Cortisol and to a lesser extent corticosterone, which increase the formation of glucose from protein, and have an antiinflammatory or antistress action. Their secretion rate is raised in response to the stress of infection, extreme exercise, or severe emotion. The administration of cortisol, or its near relative cortisone, to a person whose pituitary is destroyed is essential if they are to lead anything approaching a normal life. The secretion is controlled by a feedback running through the hypothalamus and involving CRF, a shorter feedback of cortisol acting directly on the pituitary to

inhibit ACTH secretion may also occur. The role of cortisol in normal growth is not known, at normally encountered levels it may have little effect. But excess amounts of cortisol or cortisol-like substances (cortisone, prednisone, etc.) either secreted in response to chronic stress, or given by a pediatrician for intractable asthma or other disease, have a powerful growth-retarding effect. This is manifested by small size and delayed bone age. It appears to represent a direct effect on cellular metabolism.

3 Androgens Dehydroepiandrosterone (DHA), DHA sulphate, 11β -hydroxyandrostosterone, and, in smaller quantities, androstenedione are secreted by the adrenal. In peripheral blood the main substances found are DHA sulphate and androstosterone sulphate. In urine the adrenal androgens are excreted as a number of substances collectively known as 17-oxosteroids (formerly 17-ketosteroids). Their function is apparently to cause some of the changes of puberty (discussed later) and perhaps to maintain some secondary sex characters, including muscle bulk. The stimulus to their production is not clear, ACTH does stimulate their secretion a little, but not to the extent it stimulates cortisol production. Lack of androgens is not fatal.

Whether the special fetal cortex secretes any of these substances is doubtful. It may perhaps secrete androgens, since blood levels of these are high for the first few days after birth, and at birth the level in the umbilical cord is above that in the mother's blood, signifying production by the fetus. Corticoids on the other hand, are low for the first three days after birth in both blood and urine, with maternal levels above umbilical cord ones, so these are virtually ruled out as the fetal cortex product. One theory is that the fetal cortex produces DHA, which is metabolized into estrogens in the placenta, this being the source of the very high levels of estrogen found in the pregnant woman. The evidence for this, in part, is that mothers carrying anencephalic fetuses (who lack most of their brain and have usually only small adrenal cortices) have low levels of estrogens. Apart from this, other substances may be produced by the fetal cortex, since newborns excrete a number of steroid metabolic products not seen in children or adults.

This subject has some importance in view of work during the last few years on the behavioral and endocrine effects of stimulating (originally "gentling") rats in the neonatal period. Rats who have been stimulated by handling or other means during the first few days after birth are said to show less "emotional" behavior in an open field test when adult than do unstimulated rats. They are also said to have a higher level of blood corticosterone (the chief corticoid in rats) during infancy. The idea behind this work is that a high level of corticosterone early in infancy may act to organize some area of the brain concerned with later emotional reactivity, in the same way as testosterone in the rat neonate organizes the hypothalamus in relation to later sexual activity (discussed later). But even in the rat the endocrine situation is confused at present, and transference of these results to the human has as yet no justification, particularly in view of the very considerable endocrinological and growth differences between the two species. The rat is born very much earlier in its progress to adulthood than the human, so that the first five or six days after birth in the rat correspond developmentally to somewhere in the fourth and fifth intrauterine months in the human. It would indeed be of great interest to know whether differences in stimuli reaching the human fetus affected its endocrine function in a manner that might affect, in turn, its brain development. But our ignorance about this is at present complete.

Growth hormone is secreted by the pituitary gland from about the tenth postmenstrual week. The fetal blood level, as estimated by radio-immunoassay, increases to reach a peak at about 25 to 30 weeks and appears to become less again by the time of birth. The levels are much higher than those seen in children or adults, and this would correspond with the very high fetal growth rate between 20 and 34 weeks. The chorion secretes a growth-hormone-prolactin-like substance also, but this circulates only in the maternal blood and does not apparently cross to any great extent into the fetus (Kaplan and Gumbach, 1967).

Gonadal Hormones and Sexual Differentiation

The action of genes on the Y chromosome causes the previously undifferentiated

gonad to become recognizably a testis at the ninth week of fetal age reckoned postmenstrually (or the seventh week postfertilization). Whether this is the result of hormonal action is at present uncertain. At about the eleventh postmenstrual week Leydig cells appear in the testis and increase rapidly in number until about the twenty-fourth week, after which time their absolute volume remains constant till birth, though the percentage of the whole testis they occupy declines considerably. The Leydig cells secrete testosterone or a closely related substance, and this causes the previously undifferentiated external genitalia progressively to form a penis and scrotum, beginning at the twelfth postmenstrual week (Juusek, 1967, Niemi, Ikonen, and Heivonen, 1967). Very probably the initial growth and secretion of the Leydig cells is caused by the great increase in secretion of chorionic gonadotrophin early in pregnancy. The excretion of this substance in the mother's urine reaches its peak about the tenth to twelfth postmenstrual week (where its presence is used as the basis for pregnancy tests). Chorionic gonadotrophin drops to fairly low levels by 18 weeks and it is therefore conjectured that LH from the fetal pituitary may be responsible for sustaining the Leydig cells from this age on.

In the female, differentiation of the ovary and external genitalia proceeds, it seems, more passively. In the absence of the Y chromosome, nothing happens at the ninth week and at about the tenth postmenstrual week the gonad turns into an ovary. The external genitalia become female at around the fourteenth week, apparently without hormonal intervention.

There is another aspect of this sexual differentiation, so far studied only in animals, but of much importance in man in principle and perhaps in practice too. In the rat the Leydig cell secretion acts on the brain as well as on the external genitalia. In all mammals investigated endocrinological and to a large extent behavioral maleness is dependent on the structure of the hypothalamus. If a female pituitary is grafted into an adult male whose own pituitary has been removed, then, when vascular connections with the hypothalamus have been established, the pituitary will secrete gonadotrophic hormones

in a male, not a female cycle. The converse is also true.

In the rat differentiation of the hypothalamus is caused by testosterone secreted by the Leydig cells during the first two or three days after birth. This is a true critical or sensitive period. Testosterone given a few days before birth will not cause brain differentiation, nor will testosterone given from five days after birth on to a rat whose testes were removed at birth. The message has to reach the hypothalamus at exactly the right time. A single injection of female sex hormone on the fifth day after birth will stop the proper male differentiation, and a single injection of testosterone into a female on the fifth day will produce the "androgen-sterilized female," a rat without female reproductive cycles when it becomes adult. It is known that some areas of the brain selectively take up testosterone. These must include areas concerned in sexual behavior as well as in control of gonadotrophin release. Female rats given testosterone neonatally do not show any sexual female behavior when adult, even though ovariectomized and given estrogen-progesterone replacement therapy so that their sex-hormone state is that of a normal female. If ovariectomized and given testosterone, however, they behave as males. Neonatal administration of estrogen to male rats also causes disruption of adult male sexual behavior, even when testosterone replacement is given to the adult, but this is not as complete as in the case of the female (Harris and Levine, 1965). Thus, just as in the case of the external genitalia, the female central nervous system differentiates passively shortly after birth, the male is actively organized by the secretion of the testes.

It is already clear that the rat is not an exception among mammals in this respect. To what extent and with what timing an analogous situation holds in man is not yet known. Birth in the rat corresponds probably to about the twentieth to twenty-fifth week postmenstrual age in man, though since man seems to develop Leydig cells relatively earlier than other mammals investigated, perhaps we should think in terms of about the fifteenth to twentieth week. This would in fact correspond well with fetal testosterone secretion. Whether this work has significance for human sexual behavior patterns is not

known, but it would be strange if it failed to do so. It may be that certain forms of homosexuality (assuredly not all forms) may be caused by a disturbance of intrauterine processes of this sort.

Birth to Adolescence

Differences between individuals in tempo of growth are probably mostly due to small differences in rates of secretion of hormones, themselves caused, perhaps, by differences in the setting of feedback mechanisms in the brain. Which hormones are concerned with which developmental clocks, we do not know. The smallness of the postulated hormonal differences between children is such that we could not estimate them reliably by our present chemical techniques. The general tempo may perhaps be related to differences in thyroid hormone secretion. Differences in adrenal androgen secretion may in whole or part cause the differences in skeletal maturation, but here also the levels with which such a hypothesis is concerned are below those accessible to our present methods.

The rate of secretion of *thyroid hormone* appears to drop gradually during the first two years and then remain practically constant till adolescence. So far as rate of growth is concerned, the action of the thyroid is permissive, not controlling. In hypothyroidism in childhood growth is delayed, skeletal maturity, dental maturity, and growth of the brain are all affected.

The mineralocorticoid secretion of the adrenal changes little during childhood, and the cortisol secretion rate rises gradually in proportion to the increase in body size. The secretion of androgenic adrenal hormones remains at a very low level until puberty. The response of the adrenals to ACTH however, in terms of secretion of both cortisol (chiefly) and androgens, is much the same in the child as in the adult, when differences in body size are taken into account.

The Leydig cells disappear almost entirely after birth and can hardly be identified again until puberty. The secretion of testosterone ceases or is very low, and the secretion of estrogens is also at a very low level.

Growth hormone secretion continues, perhaps decreasing slightly from its level after birth, although this is not certain. Growth hormone is not secreted continuously, but

only in response to a number of stimuli such as a rapid lowering of blood sugar, a rise in certain amino acids in the blood, physical exercise, or emotion. Thus special test situations have to be created for its estimation, and some of these preclude the use of healthy subjects. Our knowledge is thus fragmentary.

Endocrinology of Adolescence

At adolescence considerable changes in hormone secretion occur. The testes and ovaries, the adrenal and thyroid glands have an adolescent growth spurt in weight. The anterior pituitary also has a spurt, but more in girls than boys. Before puberty there is little if any sex difference in pituitary weight, after, girls have a distinctly larger pituitary, with a higher proportion of acidophil cells, probably secreting lactogenic hormone.

The first event in the sequence of puberty, immediately preceding the morphological changes, is an increased secretion of gonadotrophic hormones by the pituitary. The cells which secrete gonadotrophins cannot be seen in the pituitary before puberty in children, and bio-assay of glands also indicates that human and monkey pituitaries store very little follicle-stimulating or luteinizing hormone before puberty. This is in sharp contrast to the situation in rats, where gonadotrophin content reaches its maximum about 20 days after birth and subsequently falls until puberty, which occurs around 40 to 50 days after birth (Donovan and van der Werff ten Bosch, 1965). This is an important warning that in matters of growth and sexual development we must not be too ready to generalize from rodents to man, primates as a group differ considerably from other mammals in their patterns of growth (see Tanner, 1962, p. 233).

The rising level of FSH causes the follicles of the ovaries and the tubules of the testis to develop. Probably the rise in LH causes the Leydig cells of the testis to develop and to secrete testosterone, which in turn is responsible for many of the specifically male aspects of adolescence.

In both boys and girls there is a low and roughly constant excretion of estrogen from about 3 to 7 years, followed by a gradual rise in both sexes. As adolescence begins in girls, usually with the development of the breast bud, estrogen excretion rises very

sharply and becomes cyclic (for literature see Tanner, 1969) The values reached during the cycle continue to increase until several years after menarche In boys there is also a rise in estrogen excretion, occurring midway through puberty, at stages 3 or 4, (out of 5) of genitalia and pubic hair development The levels reached are, naturally, much lower than in girls Small amounts of estrogen continue to be excreted in adult men They probably come chiefly from the adrenal cortex and from the metabolism of other steroid hormones

In boys the secretion of testosterone greatly increases at puberty In this instance we already know something of the mechanism concerned, thanks to Lindner's (1961) work on Leydig cell secretion in the bull This mechanism has general importance, in that it probably characterizes many developmental sequences In the spermatic vein of the prepubertal calf there is a considerable amount of androstenedione, a precursor of testosterone, but very little testosterone itself Androstenedione has only a very weak androgenic action At puberty the ratio of the two substances in spermatic vein blood is changed, in adult animals testosterone greatly predominates The interesting thing is that injection of chorionic gonadotrophin (the nearest approach available to the natural stimulus, LH, at the time of the experiments) does not cause a conversion of androstenedione to testosterone, but merely an increase in androstenedione secretion Only after puberty does gonadotrophin cause an increased testosterone secretion Thus at puberty the Leydig cell acquires the capacity to convert androstenedione to testosterone, and this is by an increase in the amount of the enzyme 17 β -hydroxysteroid dehydrogenase (as has been shown in the rat by Inano, Hori, and Tamaoki, 1967) Women evidently lack the mechanism for making this change, either because it can only happen in the Leydig cell, which they do not possess, or because the activator of the enzyme is missing, perhaps for chromosomal reasons

Adrenocortical Hormones Two out of the three major groups of adrenocortical hormones circulate in the blood at relatively unchanged levels from birth on these are cortisol and aldosterone The excretion of cortisol metabolites increases in keeping with

the increase of body size, but it has no particular spurt beyond this at adolescence

The secretion of adrenal androgenic hormones, on the other hand, increases greatly at puberty, in both boys and girls Before puberty very little DHA or DHA sulphate can be demonstrated in blood or urine The androgen metabolites in the urine, that is the 17-oxosteroids, increase sharply at about the time the height spurt begins This occurs in both sexes, but in boys the 17-oxosteroids reach a level about one and a half times that in girls The sex difference is probably entirely due to the fact that testosterone is also partly metabolized to 17-oxosteroids so that the boys' levels include both adrenal and testicular androgen metabolites It seems likely that the adrenal contribution is fairly similar in both sexes At least seven distinct substances are excreted, however, and it is not known whether men and women differ in the relative proportion of each that they excrete

The cause of the increase in androgen secretion is far from clear ACTH cannot be responsible, for it always causes a much greater increase in corticoid than in androgen secretion, yet the corticoids rise only slightly at puberty Either some still unknown pituitary hormone is concerned ("adrenarche hormone") or else something modifies the response of the adrenal to ACTH at this time (see Tanner, 1962) This adrenal component of adolescence is sometimes referred to as "adrenarche" This should really read "androgen-adrenarche" since only the androgen function of the adrenal is concerned

These adrenal androgens are clearly important in bringing about some of the changes of puberty, particularly in girls, in whom they cause growth of the pubic and axillary hair Occasionally children are seen in whom pubic and sometimes axillary hair develops very early, before the occurrence of other signs of sexual maturity The patients are mostly girls and a high proportion have brain damage Bone maturation is advanced and the patients are large The condition is known as "premature adrenarche" or "premature pubarche" and is associated with levels of 17-oxosteroid excretion characteristic of late adolescents The disorder probably represents an isolated release of the hypothetical "adrenarche hormone"

The differential growth of hair at pubes, axilla, and face seems most easily explicable on the basis of locally different thresholds to stimulation, coupled perhaps with a predilection of hair at each site for either testicular or adrenal hormone. On this hypothesis, the skin of the pubes has the lowest threshold and responds to the small amount of adrenal androgen secreted by both girls and boys early in puberty. Axillary hair has a higher threshold, develops later and is somewhat more responsive to testosterone, the beard has a still higher threshold to adrenal androgens and a more pronounced preference for testosterone. This is probably an oversimplified view, a sequence of changes in hair follicle receptivity may also occur.

The cause of the adolescent growth spurt in body size is not yet known. The excess of the male over the female spurt is probably due to testosterone, as is the excess of male muscle and bone development. The rest of the spurt, common to both sexes, must be due to an increase in growth hormone secretion or to the adrenal androgens or to a combination of both. The part played by growth hormone at adolescence is not yet clear, but it should become so in the next few years, now that methods for its estimation are reliable.

Much is still uncertain about the endocrinology of adolescence. The synergies of hormone action are exceedingly complicated, the technical methods are complex and costly, and the absolutely essential longitudinal studies on hormonal production have not yet been attempted. Further details of what is known in this field can be found elsewhere (Tanner, 1969, Tanner and Gupta, 1968).

The Initiation of Puberty

The manner in which puberty is initiated has a general importance for the clarification of developmental mechanisms. Certain children develop all the changes of puberty, up to and including spermatogenesis and ovulation, at a very early age, either as the result of a brain lesion or as an isolated developmental, sometimes genetic, defect. The youngest mother on record was such a case, and gave birth to a full-term healthy infant by Caesarian section at the age of 5 years 8 months. The existence of precocious puberty and the results of accidental ingestion by small children of male or female sex hormones

indicate that breasts, uterus and penis will respond to hormonal stimulation long before puberty. Evidently an increased end-organ sensitivity plays little or no part in pubertal events.

The signal to start the sequence of events is given by the brain, not the pituitary. Just as the brain holds the information on sex, so it holds information on maturity. The pituitary of a newborn rat successfully grafted in place of an adult pituitary begins at once to function in an adult fashion, and does not have to wait till its normal age of maturation has been reached (Harris and Jacobsohn, 1952). It is the hypothalamus, not the pituitary, which has to mature before puberty begins.

Maturation, however, does not come out of the blue and at least in rats a little more is known about this mechanism. In these animals small amounts of sex hormones circulate from the time of birth, and these appear to inhibit the prepubertal hypothalamus from producing gonadotrophin release. At puberty it is supposed that the hypothalamic cells become less sensitive to sex hormones. The small amount of sex hormones circulating then fails to inhibit the hypothalamus, gonadotrophins are released, and the level of sex hormones rises until the same feedback circuit is re-established, but now at a higher level of gonadotrophins and sex hormones. The sex hormones are now high enough to stimulate the growth of secondary sex characters and support mating behavior (Donovan and van der Weiff ten Bosch, 1965).

The idea of a single feedback system operating at two different levels is very attractive, since it links with other developmental notions, and makes the evolution of the delay in primate puberty easier to comprehend. So far, however, it has been shown to be true only in rodents, although there are a few bits of supporting evidence from human pathology.

The basic change in hypothalamic receptivity at puberty remains unexplained. It may be itself a consequence of change in afferent input, though from where is not known.

VI GROWTH AND DEVELOPMENT OF THE BRAIN

We know all too little about the growth of the brain and the development of its organization. Anatomical studies of brain structure

are immensely laborious and few workers have had the courage, persistence, and technical support needed to carry out morphological analyses of the brains of children at different ages. Physiological studies are practically confined to the electroencephalogram and biochemical investigations have scarcely begun. In the last decade, however, interest has greatly increased, and mapping of the concentrations and activities of chemical substances at various stages of development has begun in animals.

Gross Morphological Development

From early fetal life the brain, in terms of its gross weight, is nearer to its adult value than any other organ of the body, except perhaps the eye. In this sense it develops earlier than the rest of the body (see Fig 6). At birth it averages about 25% of its adult weight, at 6 months nearly 50%, at 2½ years about 75%, at 5 years 90%, and at 10 years 95%. This contrasts with the weight of the whole body, which at birth is about 5% of the young adult weight, and at 10 years about 50%.

Fig 26 Percentage of their volume at birth reached at earlier months by parts of the brain and spinal cord. Cerebrum includes hemispheres, corpus striatum, and diencephalon (From Tanner, 1961, data from Dunn, 1921)

Fig 27 Percentage of total brain volume contributed by cerebrum, cerebellum, and midbrain-pons-medulla at ages from 3 postmenstrual lunar months to adulthood Cerebrum includes hemispheres, corpus striatum, and diencephalon (From Tanner, 1961, data from Dunn, 1921, White House Conference, 1933)

The gross anatomical appearance at different stages of fetal development from 10 to 41 postmenstrual weeks has been well illustrated by Larroche (1966), who also gives a comprehensive table of myelination during the fetal period. Different parts of the brain grow at different rates and reach their maximum velocities at different times. Figure 26 illustrates this (compare Fig 34 on growth gradients in the limbs). The percentages of the volume at birth are plotted for the cerebrum (including corpus callosum, basal ganglia, and diencephalon, with the thalamus and hypothalamus), the cerebellum, the midbrain, pons, and medulla, and the spinal cord. The midbrain and spinal cord are the most advanced from three postmenstrual months to birth, and the pons and medulla come next. The cerebrum is less advanced, although much ahead of the cerebellum. Contrary to the often-quoted "law" of cephalocaudal or head-to-tail development, the development of the central nervous system structures is more usually in a caudocranial

direction. The nucleus of the fifth cranial nerve, for example, first matures at its caudal end, and its head division develops later.

The percentage of the total brain volume contributed by the different parts is illustrated in Fig 27. At 3 months postmenstrual age the midbrain, pons, and medulla occupy 8% of the total volume, but by birth this has fallen to 1.5%, from 1 to 10 years the percentage increases slightly again, presumably due to growth of fiber tracts through those areas. The cerebellum grows rapidly from shortly before birth to about a year after it, thus its adult percentage value is reached late. The cerebrum first increases in percentage as it grows faster than the midbrain-pons-medulla and then decreases as the cerebellum comes to surpass it in growth rate. Among the diencephalic structures the hypothalamus, epithalamus, and subthalamus are the first to differentiate, followed by the thalamus and corpus striatum. The thalamus and hypothalamus together constitute 10% of brain volume at 3 postmenstrual months and 3% at birth, the

corpus striatum also constitutes 10% at 3 months and falls to about 5% at birth (Jenkins, 1921, Dekaban, 1954). These parts of the brain reach their maximum velocity of growth at about 2 months, the cerebral hemispheres at about 3 months, and the cerebellum at about 6 months.

Cerebral Cortex Development

Most of our knowledge about the development of the structure of the cerebral cortex is due to the enormously painstaking studies of Conel (1939, 1941, 1947, 1951, 1955, 1959, 1963), who published analyses of a small number of children at birth, 1 month, 3 months, 6 months, 15 months, 2 years, and 4 years. Rabinowicz (1967) has similarly described the 36-week premature. Further histological data for the prenatal period are given in Larroche (1966).

The cerebral cortex is identifiable at about 8 weeks, thereafter it gradually increases in width, at first uniformly, but by about 20 weeks it is increasing to different degrees in different parts (Klosowski, 1963). By about 26 postmenstrual weeks most of the cortex shows the typical structure of six somewhat indeterminate layers of nerve-cells, with a layer of fibers on the inside. The layers do not advance in maturity simultaneously, the cells of the fifth layer are the most advanced up to birth and for a little time beyond, followed in order by those of the sixth, third, fourth, and second (Rabinowicz, 1967). All the nerve cells present in the adult are thought to be formed during the first 20 or 30 postmenstrual weeks. Thereafter, it is said, the cells differentiate, axons and dendrites grow, nucleoprotein appears in the cytoplasm, and the axons acquire varying amounts of myelin as sheaths, but no new cells are formed. This view has lately been challenged, although only to the extent of supposing that a small number of new nerve cells may appear. Neuroglia, the cells of the supporting tissue, may differentiate for somewhat longer. Neuroglia outnumber neurones after the early period of development, and they eventually constitute some 90% of the cells present in the brain.

From these cellular changes a series of criteria for maturation of parts of the cortex can be developed, in just the same way as the criteria for skeletal maturity are developed from a consideration of the appearances of

the bones. Conel uses nine criteria, including the "density" of neurones (i.e., the number of neurones per unit volume of cortex), which decreases as axons and dendrites grow in between them, size of neurones, which increases, condition of Nissl substance and neurofibrils, length of axons and dendrites, and degree of myelination.

Two clear gradients of development occur during the first two years after birth. The first concerns the order in which general functional

Fig 28 Lateral and medial views of brain, to show divisions of cerebral cortex, areas of localization of function, and location of thalamus, cerebellum, pons, medulla, and spinal cord (a) Lateral view of cortex (b) Medial view of cortex and subcortical structures (From Tanner, 1961, after various maps, including Penfield and Rasmussen, 1950)

areas of the brain develop, the second the order in which bodily localizations advance within the areas. The most advanced part of the cortex is the primary motor area located in the precentral gyrus (see Fig 28). Next comes the primary sensory area in the postcentral gyrus, then the primary visual area in the occipital lobe, then the primary auditory area in the temporal lobe. All the association areas lag behind the corresponding primary ones. Gradually the waves of development spread out, as it were, from the primary areas. Thus in the frontal lobe the parts immediately in front of the motor cortex develop next and the tip of the lobe develops last. The gyrus on the medial surface of the hemisphere and in the insula are generally last to develop, the hippocampal and cingulate gyri lag behind most areas of the frontal lobe, and the insula develops later than any part of the frontal lobe examined.

Within the motor area the nerve cells controlling movements of the arms and upper trunk develop ahead of those controlling the leg. The same is true in the sensory area. This corresponds to the greater maturity of the arm relative to the leg in bodily development and also to the infant's capacity to control his arms more than his legs. The leg areas remain the least developed up to 2 years and presumably somewhat beyond. In the association areas we would not expect gradients of this sort, since little or no localization by bodily areas occurs there. Conel, in fact, describes development outside the primary areas as proceeding in a fairly uniform sequence within each lobe.

At birth the cortex is very little developed and its appearance does not suggest that much, if any, cortical function is possible. By 1 month the histological appearance of the primary motor area of the upper limb and trunk suggests it may be functioning. By 3 months all the primary areas are relatively mature, suggesting that simple vision and hearing are functional at a cortical level but not at a level involving any interpretive functions dependent upon the association areas. At this age the motor area is clearly the most advanced part of the cortex, and within it the hand, arm, and upper trunk are the most advanced parts.

By 6 months most areas have advanced further and many of the exogenous fibers coming to the cortex have become myelinated, al-

though few association fibers within the cortex are yet mature. There has been a particularly rapid development in the part of the cortex controlling eye movement. Between 6 and 15 months the rate of development is greatest in the temporal lobe and in the cingulate and insula, next greatest in the occipital, and least in the parietal and frontal lobes, which have already passed through most of their course. The primary motor area is still slightly in advance of all the others but within it the leg still remains behind the rest. The child's behavior reflects this; he is beginning to control his hands and arms quite well, but he controls his legs less successfully. Many children are unable to walk at 15 months and few do so skillfully. The visual association area has matured somewhat and is ahead of the auditory. By 2 years the primary sensory area has caught up the primary motor, and the association areas have developed further. But some areas, most notably the hippocampal and cingulate gyri and particularly the insula, are still clearly immature.

During this period from birth to 4 years and presumably for some time after, there is a continuous increase in the number and size of dendrites in all layers of the cortex, and in the number and complexity both of exogenous fibers from lower in the brain, and in association fibers within and between cortical areas. The "connectivity" (i.e., the probability of one cell influencing others through its connections with them) increases, and this is clearly of paramount importance to the exercise of the more complicated brain functions.

It is clear from the studies on myelination by Yakovlev and Lecours (1967) that the brain goes on developing in the same sequential fashion at least till adolescence and perhaps into adult life. Myelination of nerve fibers is only one sign of maturity, and fibers can and perhaps sometimes do conduct impulses before they are myelinated. But the information from myelin studies agrees well with Conel's information on nerve cell appearances where the two overlap. As a rule the fibers carrying impulses to specific cortical areas myelinate at the same time as those carrying impulses away from these areas to the periphery; thus maturation occurs in areas or functional units as we might expect rather than in geographical areas (Anokhin, 1964).

A number of tracts have not completed their

myelination even three or four years after birth. The fibers which link the cerebellum to the cerebral cortex and which are necessary to the fine control of voluntary movement only begin to myelinate after birth and do not have their full complement of myelin till about age 4. The reticular formation, a part of the brain especially developed in primates and man and concerned with the maintenance of attention and consciousness, continues to myelinate at least until puberty and perhaps beyond. Myelination is similarly prolonged in parts of the forebrain near the midline. Yakovlev suggests this is related to the protracted development of behavioral patterns concerned with metabolic, visceral, and hormonal activities during reproductive life.

Throughout brain growth from early fetal life the appearance of function is closely related to maturation in structure. It is of much interest that fibers of the sound-receiving system ("the acoustic analyzer") begin to myelinate as early as the sixth fetal month, but they complete the process very gradually, continuing until the fourth year. In contrast, the fibers of the light-receiving system or optic analyzer begin to myelinate only just before birth but then complete the process very rapidly. Yakovlev points out that in fetal life the sounds of the functioning of maternal viscera are the chief sensory stimuli, apart from anti-gravity sensation. They are evidently not perceived at a cortical level, but at a subcortical one the analyzer is working. After birth, however, visual stimuli rapidly come to predominate, for man is primarily a visual animal. These signals are very soon admitted to the cortex, the cortical end of the optic analyzer myelinates in the first few months after birth. The cortical end of the acoustic analyzer, on the other hand, myelinates slowly, in a tempo probably linked with the development of language.

There is clearly no reason to suppose that the link between maturation of structure and appearance of function suddenly ceases at age 6 or 10 or 13. On the contrary, there is every reason to believe that the higher intellectual abilities also appear only when maturation of certain structures or cell assemblies, widespread in location throughout the cortex, is complete. Dendrites, even millions of them, occupy little space, and very considerable increases in connectivity could occur within the limits of a total

weight increase of a few per cent. The stages of mental functioning described by Piaget and others have many of the characteristics of developing brain or body structures and the emergence of one stage after another is very likely dependent on (i.e., limited by) progressive maturation and organization of the cortex.

Influences on Brain Development

To what extent environmental stimulation can influence brain maturation or organization is not clear. Cajal, the great pioneer of brain histology, believed simply that use of a cell caused axons and dendrites to grow or, in modern terms, increased its connectivity. Hebb thinks the same, but there is little experimental evidence yet to support their view. Many aspects of brain maturation seem quite unaffected by variations of environmental input within the range of what we consider normal environments. Thus prematurely born children in most respects develop quite in parallel with children of the same postfertilization age growing in the uterus (see Section II), at least till the normal time of birth. Premature babies (excluding those born prematurely by reason of some severe defect) become able to stand and to walk no sooner by being exposed to the stimuli of the outside environment longer. Calculated from birth, one series of premature reached these milestones later than babies born at term, but calculated more correctly from fertilization, they reached them at just the same time (Douglas, 1956).

This is not to say by any means that maturation of the brain is unaffected by any outside conditions. Certain states, such as malnutrition or the presence of toxic substances, can certainly affect neural growth, if they are extreme. Conel remarks that at all ages some infants' brains were more myelinated than others, and that this was general over the whole cortex and not confined to any one area. He remarks also that several of the infants with the least myelin for their age had a malnourished appearance. To what extent malnutrition can in fact retard or abolish brain maturation in man is still a matter for research. It is certainly true that brain growth, both in man and experimental animals, is less affected than body growth by malnutrition at any postnatal period. This is

largely because the brain completes such a relatively higher proportion of its growth *in utero*. But to say it is less affected is not to imply it is not affected at all. In rats malnutrition certainly causes delay in brain maturation, as does lack of thyroid hormone (Eayrs and Horn, 1955, Eayrs and Lishman, 1955).

More specific environmental factors may also be important at particular times. For the human, our ignorance in this regard is complete. In some animals, however, certain neural cells seem clearly to need an environmental stimulus for maturation to occur properly. The visual system of the kitten provides an example (Hubel and Wiesel, 1963, Wiesel and Hubel, 1963). Normally a kitten opens its eyes about 8 days after birth and at this time its visual system appears to be fully functional. But if its eyes are stitched closed from before the usual opening time until 3 months, then the cells of the lateral geniculate nucleus atrophy, or at least fail to develop normally. It seems that the experience of light (not form) is necessary to put the finishing touches to these cells, or to prevent them falling back into an atrophy of disuse. Once they have experienced light, however, they can thereafter go on without it, at least for a considerable time, for stitching the eyes of adult cats for several months leaves the cells intact.

Probably each species of animal differs in the amount and nature of input from the environment required for full development of its nervous system. The environment must be relied upon to provide the right stimulus at the right time. In this sense animals are born into "expected" environments—indeed, into "required" ones. What precisely are the requirements for the human neonate we do not know. There is no doubt that in the brain associations of nerve cells, diffuse in location but linked in function, are built up progressively during the course of growth. These cell assemblies must be presumed to have a high degree of stability, though the groupings of the particular cells constituting them may change. It seems probable, but at present wholly unproven, that optimal size and permanence of an assembly is secured by giving it particular stimulation at a particular time. It seems likely, too, that assemblies built early in childhood are under most circumstances more resistant to decay or change

than later-built ones. We have no answer to the all-important question of what happens to the cell assemblies if we attempt to teach something too soon, or, conversely, if we delay teaching something too long, so that a new neural organization is starved of exercise.

Motor Development: Wetting and Walking

The development of the brain is reflected no less in motor behavior than in increasing intellectual ability. In the early years the ability to carry out motor acts is the most important guide to the child's mental development.

The sequence of motor development during infancy has been dealt with elsewhere in this book. Detailed description of the development of late motor skills is beyond the scope of this book (see Ministry of Education, 1952, for aged 5 to 11, see also Clarke and Wickens, 1962, Glasgow and Kruse, 1960). Changes in muscle size and strength at adolescence have been described in Section III. There remain a few points to be made.

Sphincter Control. In the newborn baby micturition is a reflex act, which follows handling or other nonspecific stimuli or the taking of a meal. Babies may be conditioned very early to empty the bladder when placed on a pot, but voluntary control only appears at 15 to 18 months. The first stage is when the child is aware of the imminent passage of urine and tells the mother, but too late. A little later he tells her in sufficient time for the pot to be brought. It seems that sensory development at the cortical level is as important as motor control, indeed for a much longer period the child may forget to go to the toilet when occupied with a new toy or in some absorbing play.

Most children are dry by day by 18 months, but some, although perfectly normal, not until 3 years. At night about 50% of children are dry by age 2, and about 75% by age 3. By age 5 only 90% are dry, the remaining 10% wetting the bed occasionally or regularly throughout childhood. As in most motor developments girls on average mature earlier than boys, and in a large national survey in Britain it was found that bed-wetting after age 5 occurred in 12.1% of boys but only 9.7% of girls, a highly

significant difference (Pingle, Butler, and Davie, 1966) The percentage of children who wet during the day after age 3 was the same, however, in boys (44%) and girls (43%), suggesting that the girls' advantage occurs under circumstances where conscious control is not operating

Walking The way in which the ability to walk develops has been described and illustrated in detail by McGraw (1943) At first the child develops inhibitory control over the reflex neonatal movements of the legs, then he makes stamping leg movements when supported, then deliberate forward steps when supported, then independent steps but with the arms widely extended, feet far apart, and knees flexed Only when these developments are completed does the child walk with heel-toe progression, and still later with the arms swinging synchronously with the legs

In the series of longitudinal studies in Brussels, London, Paris, Stockholm, and Zurich, coordinated by the International Children's Center, the mothers were asked at what age their child first walked a few steps without support Since they were interviewed when the children were 9 months, 12 months, 18 months, 2 years, and 3 years, they were not called on to remember over a period of longer than 6 months The age of walking, defined in this way, was distributed normally when age was expressed in logs, but not otherwise (Hindley et al., 1966) No social class differences were found, nor were any sex differences, in any of the five samples But the means of the samples differed significantly, the Stockholm children walked at an average of 12.5 months and the Paris children at 13.8 months with the others intermediate The range of normal variation of this event is about 10 months to about 19 months At least this is so for Europeans, but East African children and probably Negro children in general have considerably accelerated motor development, in Uganda many children were able to walk alone by 9 months (Geber and Dean, 1964)

VII THE ORGANIZATION OF THE GROWTH PROCESS

The growth of the child is a very regular and very organized process The potential structure of the adult organism is, for the

most part, contained in the highly condensed codescript of the genes For this reason identical twins resemble each other very closely in appearance They are not, however, absolutely the same During the long and complex process which intervenes between the primary chemical action of the genes and the finished adult form there are many opportunities for slight deviations to occur

When the single egg divides to give identical twins, it is unlikely that exactly equal amounts of cytoplasm go to each half It is therefore unlikely that exactly the same concentration of chemical reactants will be formed in the two organisms During subsequent development these differences could become progressively multiplied Then, as growth continues, the two organisms are affected differently by the environment, for their positions in the uterus and their blood supplies are never quite the same Finally, after birth, even under favorable circumstances of upbringing the two children are never identical in their total environment, for their food habits are never quite the same, their illness experiences never precisely similar Yet uniovular twins do, in fact, greatly resemble each other Their similarity, not their difference, requires an explanation

Regulation of Growth, Canalization and Catch-Up

It is thought that the processes of growth are self-stabilizing, or, to take another analogy, "target-seeking" Children, no less than rockets, have their trajectories, governed by the control systems of their genetical constitution and powered by energy absorbed from the natural environment Deflect the child from its growth trajectory by acute malnutrition or illness, and a restoring force develops so that as soon as the missing food is supplied or the illness terminated the child catches up toward its original curve When it gets there, it slows down again to adjust its path onto the old trajectory once more

It used to be thought that this self-correcting and goal-seeking capacity was a very special property of living things We now realize that complex manimate systems consisting of many interacting substances frequently show this capacity, especially if they are "open," that is, in continuous interaction with surrounding systems

The property of returning to the original growth curve after being pushed off trajectory has been called *canalization* or *homeorhesis* by Waddington (1957) (Homeostasis is the maintenance of a static situation and homeorhesis the maintenance of a flowing or developing one.)

The growth in height of a healthy, well-nourished child was illustrated in Fig 2. Figure 29 shows the effect on the growth of

a young child of two periods in which food intake was much reduced for psychological reasons. The distance curve is shown in Fig 29a, the velocity curve in part b. When food intake is restored to normal there is a period of what is called catch-up growth. The velocity during each period of catch-up reaches more than twice the average velocity for the chronological age. In this instance the catch-up is probably complete in that the child is

Fig 29 Two periods of catch-up growth following episodes of anorexia nervosa in a young child. For explanation of charts, see text (From Prader, Tanner, and von Harnack, 1963.)

Fig 29 (Cont'd)

quite normal in length and velocity of length by age 5 [The allied term "compensatory growth" is normally used to refer to growth of organs or parts rather than to the whole animal and describes a different phenomenon. Thus when one kidney is removed, the other undergoes compensatory growth or hypertrophy, when a limb of an amphibian is removed, it, or something similar, may grow again and this also may be called compensatory growth (see Goss, 1964)]

Figure 30 shows a second instance of catch-up, this time following removal of an adrenal tumor which had been secreting excessive quantities of cortisol (Cushing's syndrome). By age 4 the child was very small, but when the tumor was removed a remarkable catch-up ensued. At age 11, however, the child had only reached the twentieth percentile for height, so perhaps her regulatory forces had been insufficient to make good the effects of her long period of growth retardation.

The mechanism of canalization is at present very little understood. Females are better canalized than males, in respect of most characters, in man and all other mammals that have been investigated. Thus girls slow their growth less in response to malnutrition or disease than boys (see Tanner, 1962, p 127). We have no direct evidence on the extent of canalization in brain growth or in the development of mental abilities. However,

there seems every reason to suppose the principle applies here also, particularly at the time when the brain is developing rapidly. The fact that girls trisomic for chromosome 21 have higher IQs than trisomic boys may be an example of better female canalization of brain development in a situation of chemical stress. Heterozygotes seem also to be better canalized in respect to a number of stresses than homozygotes, to judge by the evidence from inbred strains of animals.

The earlier and the more prolonged the stress, the more difficult it is for regulation to be fully effective in restoring the prestress situation. Rats may be malnourished from birth till 21 days by being placed in an over-nutriented litter so that the mother's milk is insufficient. At weaning (21 days postbirth) they are smaller than well-fed rats. If after weaning they are allowed unlimited access to food, they do show a catch-up, but it is insufficient to bring them up to the size of the well-fed rats; they remain small throughout their lives (Widdowson and McCance, 1960). If, in contrast, rats are malnourished from 21 days to 77 days and then fed without restriction, a complete catch-up in weight occurs by 133 days in females and a very nearly complete one in males (Widdowson, Mavor, and McCance, 1964). Once again it must be remembered that the rat is born very early compared with the human, and the human equivalent to the rat suckling-period starvation is starvation *in utero*. It is indeed true that babies born at 40 weeks with an abnormally low birth weight and length fail to catch up after birth and remain small throughout their lives (see Section II).

The evidence leads us to suppose that it is both the duration of the malnutrition and the magnitude of the normal rate of growth at the time the malnutrition is applied that determine whether a full catch-up is possible. If true, this means that the critical factor is the *amount* of unsatisfied growth potential accumulated. Presumably this must be a real substance or state of the organism, and for this and other reasons, I have proposed a hypothetical mechanism for growth regulation (Tanner, 1963). The main points of the mechanism are illustrated in Figs 31, 32, and 33.

The supposition is that in the normally

developing central nervous system a substance accumulates, or some cells mature, in a manner which traces out the brain's growth curve. This is called the "time tally" in Fig 31, but in reality the tally will not signal clock time, of course, but the maturation tempo for each individual. Suppose further that body growth is also represented by some substance, called in Fig 31 "inhibitor," at present wholly hypothetical both as to nature and provenance. The normal velocity of growth may then be thought to be proportional to the "mismatch" (M in Fig 31) between these two signals, in other words, to

the "gap" in growth advancement between CNS and periphery. (In reality we should postulate a less simple system, wherein numerous heterochronic systems of this sort are operating, all interacting, but the system described is the simplest case of this.)

Figure 32 then illustrates the situation in catch-up, where catch-up can be complete. In this case we presume the CNS time tally is unaffected by the malnutrition, since the CNS grows earlier and is known, after the first weeks, to be relatively resistant to environmental perturbations. The model reproduces as it should the main feature of

Fig 30 Girl with Cushing's syndrome showing catch-up after removal of adrenal tumor at age 4. For explanation of charts, see text. (From Prader, Tanner, and von Harnack, 1963.)

Fig 30 (Cont'd)

catch-up, that is, the greater-than-normal growth velocity, since the mismatch (M_1) at refeeding is greater than the mismatch when starvation began.

If, however, starvation occurs at a time when the brain is still developing, the situation illustrated in Fig 33 may result. Here the time tally itself is affected, though less than the general bodily growth. On refeeding a complete catch-up will not occur, since the "sizerstat" has been reset. The model reproduces the threshold feature of complete catch-up described above, the faster the CNS

(or, more accurately, the area concerned with the time tally) is growing and the longer the starvation occurs, the more the sizerstat gets "bent" and the less complete is the catch-up.

This is only a hypothetical model, and it may prove to be an erroneous one so far as size regulation goes. But it is a general model of the interaction of heterochronic processes and as such has a considerable importance for the understanding of dysharmonic growth processes and for the special case of sensitive or critical periods.

Fig 31 Hypothetical relations underlying supposed growth-controlling agents (see text) The quantity M represents the mismatch signal (From Tanner, 1963)

Heterochrony and Dysharmonic Development

The multitude of chemical reactions going on during differentiation and growth demands the greatest precision in linkage. Thus for normal acuity of vision to occur the growth of the lens of the eye has to be harmonized closely with the growth in depth of the eye-

Fig 32 Velocity expected in catch-up growth, assuming control system of Fig 31. Catch-up velocity is proportional to the mismatch M_1 , which is greater than the mismatch when starvation began and equal to mismatch at an earlier age, as represented by $M_1 = M_2$ (From Tanner 1963)

Fig 33 Hypothetical explanation of incomplete catch-up following prolonged starvation. Time tally velocity is supposed to be reduced irreversibly under these conditions (see text) (From Tanner, 1963)

ball, so that the point of focus of the light rays lies exactly on the retina. It is small wonder that the success of this coordination varies, and most people are just a little farsighted or nearsighted. Again, it seems that many features of the face and skull are individually governed by genes which do not much influence the growth of other, nearby, features. But in general the parts of the face fuse to form an acceptable whole. In this case the final growth stages are plastic and variable, and in fitting together, for example, upper and lower jaws, forces of mutual regulation come into play which do not reflect the original growth curves of the discrete parts (see Kraus, Wise, and Frei, 1959).

The regulative forces harmonizing the velocity of growth of one part with that of another do not always succeed, even in arriving within an acceptable area around the target. If the original genetic forces begin by being too unbalanced, as in trisomy, normal development cannot occur.

Variation in the speed of development of different structures and functions (heterochronisms) underlie many individual differences in bodily structure. Examples are the longer arms and legs relative to trunk in men as opposed to women, or in Negroes as opposed to whites. It is an open question to what extent similar heterochronisms may explain differences in personality structure. Some psychological abnormalities or cultur-

ally excessive deviations from the average (analogous with an inconvenient degree of nearsightedness) may arise from insufficient harmonization of the speeds at which different structures and functions develop. This could occur either for genetical reasons, the child carrying, by chance, a relatively dys-harmonic set of genes, or for environmental reasons, the development of one area of the personality having been speeded up by external forces, perhaps early in childhood, while another was relatively retarded.

This general point of view, derived from experimental embryology, clearly has possibilities for behavioral research, even though it would be unwise to press the analogy too far. Not all human behavior is open to such delightfully simple explanations as that of *Oedipus anser* studied by Lorenz (1960). Domesticated strains of geese mature earlier than wild geese, and in the offspring of a wild gander and a domesticated goose dys-harmonization occurs between sexual maturation and the earlier mother-following response. The mother-following response still remains operative when the sexual response appears, and the young male bird consequently insists on copulating with its mother. Since the wild father's sexual activity arises only later in the spring, it is unnecessary that he be killed first; he remains wholly indifferent to the drama.

The behavior of children with precocious puberty provides an instructive example of an extreme, pathological degree of heterochrony, in which a fully developed endocrine system acts upon a less developed brain. Psychosexual advancement by no means keeps pace with endocrine development. The hormones need a mature brain equipped with adolescent experience to work on if adult sex behavior is to occur. This is not to say that the hormones are without effect. In one of the best-described cases to date (Money and Hampson, 1955) the psychosexual development of a boy with simple precocious puberty was at a level characteristic of his chronological age, but more energized than normally. The boy was 6½ years old, with a skeletal age of 15. He had begun to have seminal emissions at 5 and to masturbate at 6. He experienced numerous dreams involving kissing women all over the body, which he would relate only to a male interviewer, with the

air of a "roué narrating his escapades in all-male company." He had no knowledge of copulation, and overt sexual behavior toward women had never been a problem. Several women on the hospital staff, however, said they felt uncomfortable under his gaze, which carried a considerable message of seduction.

Sensitive or Critical Periods

The much-discussed critical periods are extreme examples of the linking of differential growth events previously discussed. By "critical period" we mean a certain stage of limited duration during which a particular influence, from another area of the developing organism, or from the environment, evokes a particular response. The response may be beneficial, indeed perhaps essential to normal development, or it may be pathological. The term "sensitive period" is now displacing the term critical period. This describes the usual situation more accurately, since usually these periods consist of a number of hours, days, or weeks, during the beginning and end parts of which the organism is slightly sensitive to the specific influence, with a period of maximum sensitivity in the middle. It is not as a rule an all-or-none phenomenon.

Two examples of sensitive periods have already been given. One concerned the sexual differentiation of the hypothalamus in the rat, the other the differentiation of the external genitalia in the male mammal. Sensitive periods have long been part of the embryologists' conceptual apparatus. A tissue is said to show "competence" to a stimulus at a defined time, and to lose this competence as maturation progresses.

Sensitive periods may be times of particular vulnerability of the organism, though more in the specific than the general sense. If male sex hormone is not secreted by the testes of the neonatal rat, the hypothalamus is forever damaged. Thus the neonatal rat is especially vulnerable at this time to testicular disease or damage. But he may not be particularly vulnerable to the general stress of malnutrition, for malnutrition slows down the whole of development, so that the hypothalamus may wait, and the sensitive period, considered in clock time, may be lengthened. If the hypothalamus slows down less than the testicular development, after a time given

by the difference between the development rates of the two systems, the sensitive period passes and the developmental disaster has occurred. We are seeing again an example of heterochronism.

The period of vulnerability has particularly been discussed in relation to brain development. Flexner (1952) and others have suggested that the period during which the brain is growing at its maximum speed and acquiring many enzyme systems is a specially vulnerable one. This is at about 41 to 45 days postfertilization in the guinea pig, and in the second week after birth in the earlier-born rat. However, the degree to which various stresses and deprivations can irreversibly affect brain structure at this time is not yet certainly known.

Sensitive periods in bodily development in general seem to be less in evidence during postnatal growth, although this may only reflect on our inability to detect them. If they continue to occur during the postnatal growth of the brain, they may well be of the greatest concern for educationists. Indeed, it is widely

believed, on educational grounds, that periods of sensitivity to various environmental sensory inputs do indeed exist, whether or not these are linked with or caused by underlying sensitive periods in brain maturation in structure. Certainly there is a formal analogy between "readiness" to read, for example, and competence in brain systems. It seems likely the connection will be shown to be more than formal when research on brain growth has advanced.

Growth Maturity Gradients

One way in which the organization of growth shows itself is through the presence of maturity gradients. One such is illustrated in Fig. 34. In Fig. 34*b* the percentage of the adult value at each age is plotted for foot length, calf length, and thigh length in boys. At all ages the foot is nearer its adult status than the calf, and the calf is nearer than the thigh. A maturity gradient is said to exist in the leg, running from advanced maturity at the far end of the limb to retarded maturity at the end nearest the trunk. The word gra-

Fig. 34 Maturity gradients in upper and lower limbs. Length of segments of limbs plotted as percentage of adult value. Note hand is nearer adult value than forearm, and forearm nearer than upper arm at all ages, independent of sex difference in maturity (From Tanner, 1962, data of Simmons, 1944.)

dient has arisen because of the supposed mechanism by which this occurs. It is thought that in the embryonic limb bud, before any differences between the three segments can be discerned, there must be differences in the concentration of some chemical substance. Thus a concentration gradient of the chemical substance leads eventually to a maturity gradient in developing physical structure.

Figure 34a illustrates the same gradient in the arm, together with the fact that girls are more advanced toward maturity than boys, without this affecting the gradient within the limb.

Many other growth maturity gradients are known, some covering small areas only and operating for short periods, others covering whole systems and operating throughout the whole of growth. The head is at all ages in advance of the trunk and the trunk in advance of the limbs. In the hand and foot the second digit is the most advanced, and the third, fourth, and fifth follow in that order.

Much of the growth of the brain is organized by means of such gradients, and several have already been described in Section VI.

Stages of Development General and Singular

In child development there has been much argument as to whether development is continuous or whether it occurs in stages. Again, supposing stages do exist, there is argument as to whether any *general* ones occur, characterizing a simultaneous achievement of a number of anatomical, physiological, and psychological developments.

In physical growth, there is continuity and little evidence for discrete stages. Even in the development of motor skills such as crawling and walking development is more continuous than sudden. It is sometimes said that a child walks or does not walk, in a tone which implies that one day the child, previously unable to walk at all, suddenly finds the ability to walk unaided. Close observation of the development of such an ability, however, by no means supports this notion (McGraw, 1943), on the contrary, the ability to walk develops gradually.

In some creatures, such as insects at metamorphosis, general stages of development do occur. But in man only at adolescence do we have anything approaching a general stage,

here, it is true, developments in anatomy, physiology, and behavior tend to occur synchronously. But even here the degree of synchrony is only relative. Skeletal age and dental age are largely independent of each other, and the spurt in bodily development is not matched by any great rise in intellectual capacity.

Physical development is best envisaged as a series of many successive processes, overlapping one another in time and linked loosely or tightly as the case may be. Out of the complexity of the linkages, under equilibratory forces, emerges an overall order with visible changes in the varying sections following one another with the regularity of a continuously changing mosaic. The process is one of continuous unfolding and movement, with speeds varying from time to time in different parts of the mosaic, it is not a series of kaleidoscopic bumps. Only in certain restricted areas do rapid reassortments of the pieces occur, as they fall into new and increasingly precise patterns.

Spirals of Development

To conclude this general discussion we may revert to an example given earlier. At adolescence the great increase in sex hormone secretion is accomplished and controlled, it seems, by the use of a previously established feedback circuit, now elevated to greater levels at all points. The evolutionary and developmental usefulness of such a mechanism (compare "ritualization" in behavior) is obvious. We may call it developmental "spiralling." It is appropriate to call attention to its occurrence here, because it has theoretical relevance to psychological development. It seems likely that behavioral patterns also develop by reverberation and amplification of earlier-laid-down behaviors, perhaps with the objects changed and the emotions re-named. The analogy with physical development may be close, its pursuance may lead to increased knowledge of what is permanent and what changeable among the mechanisms of the brain.

VIII INTERACTION OF HEREDITY AND ENVIRONMENT IN CONTROLLING GROWTH

Factors affecting the rate of growth must be considered separately from factors affect-

ing the size, shape, and body composition of the child. The genetical control of rate seems to be independent of the genetical control of final size and, to a large extent, of shape (to be discussed later), and environmentally produced changes in rate do not necessarily produce any alteration in final physique. Size and shape are themselves to a large extent affected separately by genetical and environmental influences.

Rate of growth at any age is the outcome of the interaction of genetical and environmental factors. Some of the factors, like season of the year, are short-term ones reflecting the immediate environmental conditions, others, especially but not exclusively the genetical ones, are longer term and act by hastening or retarding physiological maturation from an early age. Others, such as socioeconomic class or the number of children in the household, reflect a complicated mixture of hereditary and environmental, physiological and behavioral influences.

Final size and shape also reflect the continuous interaction of hereditary and environmental forces. It is a long way from the possession of a certain set of genes to the acquisition of a height of 6 feet or the development of the menarche at age 12.5. Furthermore, as explained in Chapter 7, it is a truism in modern genetics that this interaction may be nonadditive. This means bettering the nutrition by a fixed amount will not in principle produce an increase of 10%, say, in the height of all persons but only in persons of certain "susceptible" genotypes. It is therefore impossible to specify in general the relative importance of heredity and environment in contributing to the variance of a particular trait. The nearer optimal the environment, the more the genes have a chance to show their hand, it is true, but this is a general statement only and undoubtedly many subtle and specific interactions occur, as explained in the previous section.

Hereditary factors are however, clearly of immense importance in the control of growth. The fundamental plan is laid down very early. An immature limb-bud removed from a fetal or newborn mouse and implanted under the skin of an adult mouse of the same inbred strain will continue to develop until it closely resembles an adult bone. Furthermore, the cartilage scaffolding of the bone, removed at a stage preceding actual bone formation, will

do the same (Felts, 1959). The structure of the adult bone, in all its essentials, is implicit in the cartilage model of months before. The later action of the bone's environment, represented by the muscles pulling on it and the joints connecting it to other bones, seems limited to the making of finishing touches.

Genetics of Growth

The genetical control of rate of growth is manifested most simply in the inheritance of age at menarche. Identical twin sisters growing up together under average West European economic conditions reach menarche an average of 2 months apart (see Tanner, 1962). Nonidentical twin sisters, with the same proportion of identical genes as ordinary sisters, reach menarche on average about 10 months apart. The sister-sister and mother-daughter correlation coefficients for menarcheal age are both about 0.4, which is only slightly below the same correlations for height. Thus a high proportion of the variability of age at menarche in populations living under European conditions is due to genetical causes. The inheritance is probably transmitted as much by the father as the mother, and is due not to a single gene, but to many genes, each of small effect.

This genetical control evidently operates throughout the whole process of growth, for the conclusions regarding age at menarche apply also to skeletal maturity at all ages. Reynolds (1943) calculated the correlations for age of first appearance of 38 epiphyseal ossification centers in twins, sibs, and first cousins. In 6 pairs of identical twins the correlation was 0.71, in 22 pairs of sibs 0.28, and in 8 pairs of cousins 0.12. Garn and Rohmann (1962) were able to report from the unique Fels Research Institute data parent-offspring correlations in age of epiphyseal appearances in the first five years; they vary from 0.2 to 0.5. Some bones were more subject to hereditary influence than others. Hewitt (1957) found a sib-sib correlation of 0.45 in a composite measure of bone age in the hand and wrist over the whole period birth to age 5. Sibs also resembled each other in the shape of their velocity curve of skeletal maturation, that is, in whether they gained much in the first 3 years and little in the next 2, or vice versa.

The age of eruption of the teeth is to a large extent genetically controlled (Garn, Lewis, and Kerewsky, 1965). So also, and

Fig 35 Growth in height of three sisters (a) Height plotted against chronological age (b) Height plotted against years before or after year of peak height velocity Note the coincidence of curves of F2 and F4 when equated for developmental age (part b) (From Tanner, 1962, data Ford, 1958)

to an even greater extent, are the *sequences* in which the ossification centers and the teeth appear (Garn, 1962, Garn, Lewis, and Polachek, 1960) The manner in which this occurs implies the existence of genetically controlled factors acting locally on one or a few teeth only, an example of local growth maturity gradients, discussed in the previous section (see Tanner, 1960)

Sex-linked genes appear to be concerned in both time of eruption and final size of the teeth (Garn, Lewis, and Kerewsky, 1965a,b) The evidence for this is that for tooth size the sister-sister correlation is 64, brother-brother 38, and sister-brother 21 (see Chapter 7) The same may perhaps be true of some aspects of skeletal development, but it is very hard to disentangle in these data the relative importance of sex-linkage, sex-control, and the greater regulating power of the female

Under reasonable environmental conditions the genetical control extends down to many of the details of velocity and acceleration curves of growth This is demonstrated by the records of three sisters given in Fig 35 In Fig

35a the heights are plotted against chronological age, and in part b they are plotted against developmental age as given by years before or after peak height velocity at adolescence Two of the sisters have curves which are practically superimposable except that they are on a different time base, one being almost a year in advance of the other These two therefore differ radically in one parameter of their growth curve, but little in the other parameters The third sister differs little from the others in velocity when plotted against developmental age, but markedly in actual height

There is considerable evidence that in general genes controlling rate of growth are wholly or mostly independent of those controlling the final size attained Body shape, however, as distinct from size, is somewhat related, under normal circumstances, to rate of growth There are differences in physique between those who mature early and those who mature late, and these differences can be seen both before adolescence has started and after it is over (during adolescence they are obscured or magnified by the early mature being larger

and more muscular simply because of the spurt itself) Among boys, those with muscular physiques (i.e., high in mesomorphy, Sheldon, 1940) mature on average early, those with linear physiques (high in ectomorphy) mature late. Linear, ectomorphic girls also mature late, but early-maturing girls include both the muscular and the fat individuals (or, more accurately, those high in endomorphy).

It would be wrong, however, to leave the impression that the adolescent spurt, whether occurring early or late, causes any radical change in body build. It adds only the finishing touches to a physique that is recognizable years before. Anyone who has looked at serial pictures of children followed from infancy to adulthood must be impressed chiefly by the similarity of shape the child shows from one age to the next. There is little doubt that someone used to looking at children's photographs could predict with accuracy the adult somatotype from a picture taken at age 5 or even earlier.

Not all genes are active at birth. Some are not switched on till later and some can express themselves only in the physiological surroundings provided by the later years of growth. The effects of the latter are said to be "age-limited."

This is the probable explanation of the curve described by the correlations between measurements of a child at successive ages and his measurements as an adult, which have been obtained in long-term longitudinal studies. The curves for height are illustrated in Fig. 36. The correlation of length at birth with adult height is very low, since birth weight reflects uterine conditions and not fetal genotype (see Section II). The child's genes increasingly make themselves felt and the correlation rises steeply during the first three years. After this a small, steady rise occurs till adolescence, at this time the correlation for height drops, simply because some children are early and others late developers. If skeletal age is used instead of chronological age the correlation continues to rise gradually.

The correlation coefficients between the height of the parent and the height of the child at successive ages from birth describe very similar curves. The correlation when the child is born is about .25 and it then rises to reach a plateau by the time the child is about 3. The child's resemblance to his parents in size (relative, of course, as well as absolute) becomes increasingly marked as he grows older. The same types of curves are seen in the development of resemblance in IQ. Most data on height show mother-daughter correlations

Fig. 36 Correlations between adult height and heights of same individuals as children. Sexes combined lines (0-5) from 124 individuals of Aberdeen study (Tanner, Healy, Lockhart, MacKenzie, and Whitehouse, 1956) with + points from Bayley (1954). Boys' and girls' lines (3-17) from 66 boys and 70 girls of California Guidance Study (Tuddenham and Snyder, 1954). All data pure longitudinal. (From Tanner, 1962.)

to be above mother-son correlations at all ages up to puberty (Tanner and Israelsohn, 1963, Gain, 1966). The father correlations are less precisely estimated, since it is much harder to persuade the fathers to attend for measurement, and relying on their own estimates of their height is hazardous. In general, however, it seems that the father-son correlations during childhood may be above the father-daughter ones.

Little is known about the genetics of the magnitude of the adolescent spurt. Since there is a considerable degree of independence between the amounts of growth before and during adolescence, it seems quite possible that newly acting genes may come into play at this time.

Race and Ecological Conditions

There are racial differences in rate and pattern of growth, leading to the racial differences seen in adult body build. Some of these are clearly genetically controlled, whereas others depend perhaps on climatic differences and certainly on nutritional ones (see Tanner, 1966a, for review).

We must suppose that in each of the major populations of the world the growth of its members was gradually adjusted, by means of selection, to the environmental conditions in which they evolved. We should be able to see the remnants of this process in modern populations—the remnants only, because relatively recent migrations have much altered the distributions of peoples, so that many no longer live in the areas in which they evolved. There is, in fact, a quite close positive relation between the linearity of peoples, as judged by their adult weight for height, and the average annual temperature of where they live (Roberts, 1953, Schneider, 1957).

Hiernaux' (1963, 1964) study of the growth of two East African groups living in Rwanda is especially interesting. The Tutsi are tall, linear people, with an average male height and weight of 176 cm and 57 kg, the Hutu are shorter and stockier, with averages of 167 cm and 58 kg. The Tutsi could be taller either because they go on growing for a longer period of time, or because they are longer at birth and grow at a slightly greater rate throughout childhood, ending their growth at the same time. The second possibility is in fact what occurs. Both Tutsi and Hutu grow slowly

compared with Europeans, probably because their nutrition is suboptimal, but both have menarche at about 16.5 years and show the reversal of boys-taller to girls-taller at the same age of 14 years. When the study was made (1957-1958) both groups were growing up in the same environment, but the Tutsi were better nourished, being the ruling caste.

It is clearly established that Negroes are ahead of whites in skeletal ossification at birth. This probably reflects an inherited difference in hormone secretion during the late fetal period, for Negroes' permanent teeth also erupt earlier, and the basis of these is laid down *in utero*, though later than the primary teeth, whose eruption differs less between the races. The Negro child maintains his advancement (which is paralleled by advancement in motor development) for about two or three years if living in good economic circumstances. After this the African child comes to equal, or more usually to fall behind the European in maturity. This may be a natural occurrence, the mean velocity curves of the two races having different shapes, just as do the velocity curves of males and females in both races. Or it may reflect simply the better nutrition of the European.

The extent to which nutrition, climate, altitude, and other ecological conditions are the causes of the differences between populations is not known. We must presume that these ecological features originally governed the selection of growth-controlling genes and hence led to the emergence of the differences we see now. It seems improbable that many of the differences in growth pattern are directly due to the action of climate and altitude on the growing individual, except in such instances as emphysematous chests in very high altitude dwellers. A test of this is provided by people of one race who grow up in the area mostly inhabited by another. Europeans reared in the Sudan do not grow up with the Nilotic physique, nor do Africans reared in Liverpool grow thick, European-type calves. Englishmen who pass their youth in Japan are not, so far as we know, characteristically short-legged. But there are few actual studies on these lines. Eveleth (1965) found some differences in size and to a lesser extent in body shape between American children living in the subtropical climate of Rio de Janeiro (and conserving their American food habits) and chil-

dren of apparently comparable social groups living in the United States. It is very hard to be sure of true comparability, however. Indeed all studies of migrants are presented with two great difficulties. First, migrant parents seem never to be a random sample of the population they leave, being usually larger and more intelligent than the stay-at-homes (even if they only migrate from one English county to another), and second, food habits and opportunities are seldom the same in migrants and sedentes.

We have to distinguish between ecological effects on differential body growth, leading to adults with different shapes and body compositions, as described above, and ecological effects on overall rate of growth and maturation. The two may interact but do not necessarily do so. So far as growth rate is concerned, climate, contrary to popular belief, has probably little effect. The average age of menarche of well-off Buganda girls in East Africa is 13.4 years, that of Burmese and Assamese girls living under good nutritional and medical circumstances but with a hot weather temperature of 112°F is 13.2 years (see Tanner, 1966b). These figures are entirely comparable with averages for Europe (discussed later).

Eveleth's (1966) American children reared for several years in Rio de Janeiro erupted their permanent teeth a few months earlier than their American-living controls, but they reached menarche at a very similar age (12.6 years). In girls of the same race and population there is little real evidence that climate is responsible for a significant amount of variation in menarcheal age. Altitude has been considered to slow up growth, but in studies to date it has been impossible to separate the effects of altitude itself from those due to the relative undernutrition which everywhere characterizes people living in mountainous areas (Valsik, Stukovsky, and Bernátová, 1963; Wuist, Wassertheurer, and Kimeswengen, 1961).

Season of the Year

In most European and American data a well-marked seasonal effect on velocity of growth can be seen. Growth in height is fastest in the spring and growth in weight fastest in the fall. This effect is illustrated by the growth curves of a pair of identical twins reared together, seen in Fig. 37. The average velocity of height in the March to May quarter is almost twice that in the September to Oc-

Fig. 37 Growth in height of identical twin girls, showing seasonal effect on rate of growth (From Tanner, 1962)

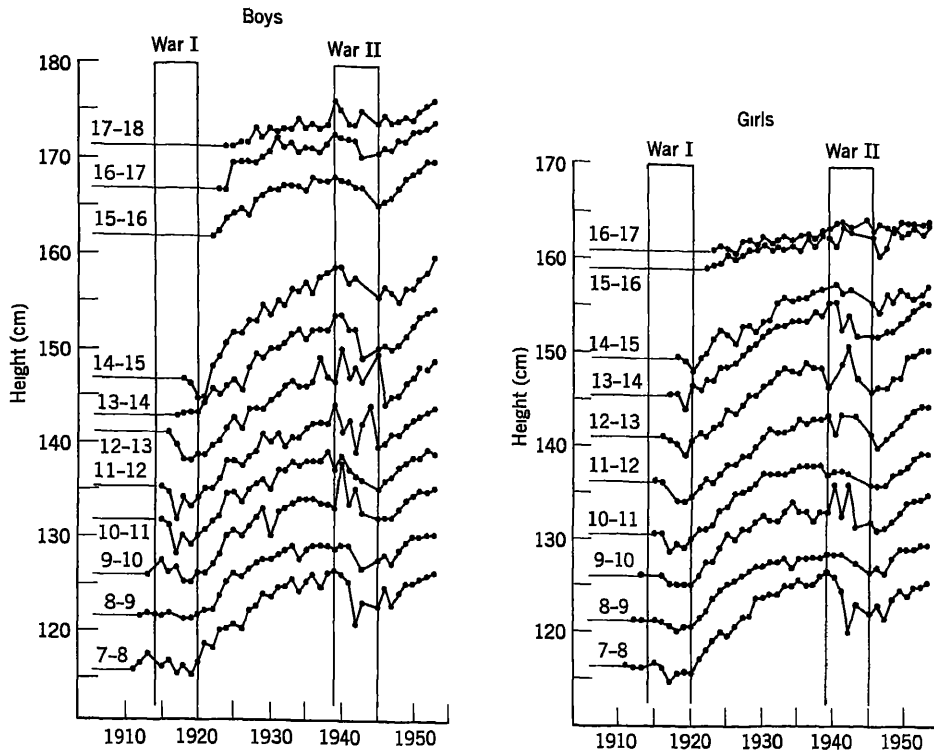

Fig 38 Effect of malnutrition on growth in height Heights of Stuttgart schoolchildren (7-8 to 14-15 Volksschule, 15-16 up Oberschule) from 1911 to 1953 Lines connect points for children of same age and express secular trend and effect of war conditions (From Tanner, 1962, data from Howe and Schiller, 1952, and personal communication)

tobes quarter in most of the older European data. Children differ surprisingly, however, both in the time of year at which they grow fastest, and in the degree to which they show the seasonal trend at all. The differences probably reflect individual variation in endocrine and hypothalamic reactivity. In countries where malnutrition is rare seasonal effects can occur, of course, for purely nutritional reasons (see Billewicz, 1967).

Nutrition

Malnutrition delays growth, as is shown from the effects of famine associated with war. In Fig 38 the heights of children in Stuttgart, Germany, are plotted at each year of age, from 1911 to 1953. There is a uniform increase at all ages from 1920 to 1940 (see discussion of secular trend following), but in the later years of both world wars the height drops as the food intake of the children becomes restricted.

Children subjected to an episode of acute starvation recover more or less completely by virtue of their regulative powers (see Section VII), provided the adverse conditions are not too severe and do not last too long. Chronic malnutrition is another affair. Most members of some populations, and some members of all populations, grow to be smaller adults than they should, because of chronic undernourishment during all or most of their childhood.

We should distinguish nutritional effects on rate of growth, on final size, and on shape and tissue composition. Size and rate are much more easily affected than shape and tissue composition, so that in malnutrition shape changes seldom occur before size and rate changes are pronounced. Differences in gene complex between different populations seem most frequently to affect shape and tissue composition, thus we have some guide as to the likelihood of a given population difference being due mostly to genetic influences or

mostly to starvation and disease. The responses of the boys and girls to chronic malnutrition, as we have already noted, are different, boys being more easily affected.

At one time it was thought that acute or chronic malnutrition changed body proportions, producing short legs relative to the trunk. The notion arose through a supposed analogy with effects in cattle. It has never been shown to be true in man. One good piece of evidence comes from Greulich's (1957) study of Japanese children reared in California compared with those reared in a worse environment in Japan. The California-reared children were bigger at all ages, but the relationship of sitting height to leg length was practically the same throughout growth under both conditions (as shown by plotting the data on standard charts for British children). In general the proportion of limb to trunk, which varies so much from one population to another, is strongly regulated by genetic programming to a degree that overall body size certainly is not.

Whether chronic malnutrition or acute malnutrition *in utero* or during the first one or two years after birth can affect brain growth and development permanently is a question of much importance. It is by no means yet settled.

The endocrine changes in malnutrition have recently been much clarified. Contrary to what was once thought, adrenal cortex secretion seems to be unaffected, and the secretion of growth hormone is increased, in a manner that agrees with the predictions of the model of growth regulation described above, on the presumption that growth-hormone secretion is proportional to the mismatch signal.

Disease

Minor and relatively short illnesses such as measles, influenza, antibiotic-treated middle ear infection, or even pneumonia cause no discernible retardation of growth rate in the great majority of well-nourished children (Tanner 1962, Meredith and Knott, 1962). In children with a less adequate diet they may cause some disturbance, though this has not been securely established. Often children with continuous colds, ear disease, sore throats, and skin infections are on average smaller than others, but inquiry reveals that they come from economically depressed and socially dis-

organized homes where proper meals are unknown and cleanliness too much trouble. The small size is more likely to be due to malnutrition than to the effects of the continued minor disease (Miller, Court, Walton, and Knox, 1960).

Major diseases which take the child to a hospital for a month or more or keep him in bed at home for several months may cause a considerable slowing down of growth, followed by a catch-up when the disease is cured. The mechanism of the retardation probably varies from one disease to another, in some an increased secretion of cortisol may be the cause.

Reports on the effects of eradicating chronic diseases such as hookworm and malaria in parasitized populations are now beginning to appear. In general the results on growth are not spectacular. Thus reduction of the incidence of malaria in a heavily parasitized population in Tanganyika did not result in any significant increase in the weights of children during the first 18 months after birth (Diaper and Draper, 1960, also see Tanner, 1966a, for additional evidence). Disease which reduces the amount of hemoglobin in the blood reduces growth rate, as do some diseases of the kidneys. But much more of the slowing of growth in underdeveloped countries is due to malnutrition than to disease, probably.

Acheson (1966) thinks that even a relatively mild disease or subnutrition will cause the formation of new cartilage to slow down while permitting the turning of cartilage into bone to continue. Such an imbalance would result in a reduced final height. While this probably occurs in severe disorders, there is little evidence that it occurs in mild diseases or temporary undernutrition.

Psychological Disturbance

Really severe psychological stress seems capable of retarding growth. In a famous experiment, Widdowson (1951) studied (as she thought) the effects of increased rations on orphanage children living on the poor diet available in Germany in 1948. The design of the experiment (see Fig. 39) was to give orphanage B a food supplement after a six-months' control period and to compare the growth of the children there with those in orphanage A, which was not to be supplemented. As shown in Fig. 39, however, the

Fig 39 Influence of sister-in-charge S on growth in weight and height of orphanage children Presence of S marked by X plots, increased rations by == Orphanage B diet supplemented at time indicated by vertical bar, but sister simultaneously transferred to B (---) from A (—) Note magnitude of growth follows presence or absence of sister, not amount of rations The curves --- are for eight favorites of sister, transferred with her to B from A (From Tanner, 1962, redrawn from Widdowson, 1951)

result was just the reverse of that expected. Though the children in B actually gained more weight and height than the children in A during the first six, unsupplemented months, they gained less during the second six months, despite taking in a measured 20% more calories.

The reason appeared to be that at precisely the six-month mark a certain house-sister had been transferred from A to become head of B (see the figure). She ruled the children with a rod of iron and frequently chose meal times to administer to individual children public and often unjustified rebukes, which upset all present. An exception was the group of eight favourites (squares in Fig. 39) whom she brought with her from orphanage A. These eight always gained more weight and height than the others, and on being supplemented in B gained still faster. "Better," quotes Widdowson, "a dinner of herbs where love is than a stalled ox and hatred therewith."

Recently an extreme clinical form of pre-

sumably the same phenomenon has been described under the name of "deprivation dwarfism." Certain very small children appear to have become dwarfed by switching off their release or synthesis of growth hormone under the stress of wholly broken-down family relationships and much individual psychological trauma. These children eat and drink compulsively to an excessive degree (the disorder is also known as the "garbage-can syndrome" since many of the children take food from the garbage) and become fat as well as dwarfed. They sleep poorly and are mentally backward. When simply removed from their environment into a sympathetic orphanage or foster home they show a marked catch-up in growth and a return to normal levels of secretion of growth hormone, without any other treatment (Powell, Brasel, and Blizzard, 1967; Powell, Brasel, Raiti, and Blizzard, 1967).

It is important to realize that both in Widdowson's example and in the clinical cases the psychological stress was severe. There is

Fig. 40. Relation between height and weight of 11-year-old children and number of children in family in different socioeconomic classes in Scotland in 1947. Classes marked 1-3, 4, 5, 6, and 7 (From Tanner, 1962, data from Scottish Council for Research in Education, 1953)

Fig 41 Percentage of daughters of skilled manual workers under 5 feet 1 inch tall taking non-manual and manual jobs and marrying men in nonmanual, skilled manual, and unskilled manual occupations (From Tanner, 1962, redrawn from Thomson, 1959)

no evidence that the ordinary ups and downs of family and school life have any effect on a child's growth

Socioeconomic Class Number of Children in Family

Children from different socioeconomic levels differ in average body size at all ages, the upper groups being larger (Tanner, 1962, Giffai and Corbier, 1966). In most studies socioeconomic status has been defined according to father's occupation, though in recent years it is becoming clear that in many countries this does not distinguish people's living standards or style of living as well as formerly. An index reflecting housing conditions is a necessary adjunct, as is some measure of the child-centeredness of the family budget.

The difference in height between children of the professional and managerial classes and those of unskilled laborers in Britain is currently about 1 inch at 3 years rising to nearly 2 inches at adolescence (this is approximately equivalent to 20 years of secular trend). In weight the difference is less, since the lower socioeconomic class children have a greater

weight for height, due to greater relative breadth of bone and muscles. In Fig 40 the heights and weights of a random sample of all 11-year-old Scottish children are plotted in relation to socioeconomic class and number of children in family. Classes 1 to 3 here represent professional persons, employers and salaried staff, class 4 nonmanual wage earners, and so on down to class 7, unskilled manual workers. The tendency for the better-off children to be larger is visible in families of all sizes.

Part of the socioeconomic height difference is due to earlier maturation of the well-off, though some is due to their being larger as adults. The difference associated with number of siblings probably is entirely due to rate of growth and disappears when adult size is reached (for full discussion see Tanner, 1966c). In most data there is a difference of age of menarche of around 2 to 4 months between girls in the best-off and worst-off classes in European countries, although the latest British data show no difference at all despite a persisting height difference (Douglas and Simpson, 1964).

The causes of the socioeconomic differential

are multiple and complex. Differences in nutrition are certainly important, and all the habits of regular meals, sleep, exercise, and general organization that distinguish, from this point of view, a good home from a bad one. The growth differences are more related to home conditions than to the economic conditions of the families, and home conditions reflect to a considerable degree the intelligence and personality of the parents. It is perhaps therefore not altogether surprising that more intelligent children are at all ages taller than less intelligent children of the same occupational background. This association probably represents a complex mixture of environmental and genetical effects, the one reinforcing the other. There is evidence that the height differential between social classes in the adult population is kept in existence by a system of social mobility which for some reason produces an average movement of tall persons upward and short persons downward (Schneider, 1964, Tanner, 1966c). The most striking demonstration of this is shown in Fig. 41, taken from the work of Baird and his associates in Aberdeen (Scott, Illsley, and

Thompson, 1956, Thomson, 1959). In 1950-1957 they measured the height of some 7500 women pregnant for the first time and showed that whatever the occupation of the father, the taller women take before marriage a more skilled job and the shorter a less skilled job, and whatever the job before marriage the taller women marry husbands with more skilled jobs and the shorter women husbands with less skilled jobs.

The differential effect of the number of children in the family is presumably mainly nutritional. At least in the poorer groups of the population the more mouths to feed and children to bother about, the less well the feeding, and perhaps the general care, is carried out. Also, in many populations larger families characterize the less intelligent section of the community.

Secular Trend

During the last hundred years there has been a striking tendency for children to become progressively larger at all ages (Tanner, 1966b). This is known as the "secular trend." The magnitude of the trend in Europe and

Fig. 42 Secular trend in growth of height. Height of Swedish girls and boys measured in 1883 (lower curve) and in 1938-1939. Elementary schools 7-14, secondary schools, 10-18. Distance curves, cross-sectional. (From Tanner, 1962, data from Broman, Dalberg, and Lichtenstein, 1942, Tables 11-14.)

Fig 43 Secular trend in height of French university students during 1940s. Average of all men students, mixed longitudinal data, according to year of birth. Note greater maximal height in more recently born, and earlier approach to maximum (From Tanner, 1962, redrawn from Aubenque, 1957)

America is such that it dwarfs the differences between socioeconomic classes. In Fig 42 are plotted the heights of Swedish boys and girls measured in 1883 and 1938. The difference amounts to about $1\frac{1}{2}$ years of growth. At the age when growth ceases, as shown by the 18-year-old girls in the figure, the secular trend is less than in childhood, but it still exists.

The data from Europe and America agree well from about 1900, or a little earlier, to the present; children in average economic circumstances have increased in height at age 5 to 7 by about 1 to 2 cm each decade, and at 10 to 14 by 2 to 3 cm each decade. Preschool data show that the trend starts directly after birth and may, indeed, be relatively greater from age 2 to 5 than subsequently. The trend started, at least in Britain, a considerable time ago, because Roberts, a factory physician, writing in 1876 said that "a factory child of the present day at the age of nine years weighs as much as one of 10 years did in 1833—each age has gained one year in forty years." The trend in Europe is still continuing at the time of writing (1967) but there

is some evidence to show that in the United States the best-off sections of the population are now growing up at something approaching the fastest possible speed.

During the same period there has been an upward trend in adult height, but to a considerably lower degree. One of the difficulties is that in earlier times final height was not reached till 25 years or later, whereas now it is reached at 18 or 19. Figure 43 shows this for French students. Those born in 1925 grew very considerably from 17 to 18, in contrast to those born in 1933. The difference between these two groups at age 17 is considerable, but at maximal adult height, aged 20, much less. Data do exist, however, which enable us to compare fully grown men at different periods. They lead to the conclusion that in Western Europe men increased in adult height little if at all from 1760 to 1830, about 0.3 cm per decade from 1830 to 1880, and about 0.6 cm per decade from 1880 to 1960. The trend is apparently still continuing in Europe.

Most of the trend toward greater size in children reflects a more rapid maturation, only

Fig 44 Secular trend in age at menarche, 1830-1960. Sources of data and method of plotting detailed in Tanner, 1962

a minor part reflects a greater ultimate size. The trend toward earlier maturing is best shown in the statistics on age at menarche. A selection of the best data is illustrated in Fig 44 (the sources are detailed in Tanner, 1966b). The trend is about 4 months per decade since

1850 in average sections of Western European populations. Well-off persons show a trend of about half this magnitude, having never been so retarded in menarche as the worse-off.

The present-day ages of menarche for various groups are given in Table 1. These data are all selected as being modern and highly reliable. They were obtained, with few exceptions, by the most valid method for collecting menarche data. This is to make a survey of a properly-selected population of girls aged 10 to 16, simply inquiring their age and whether or not they have yet menstruated. The resulting data, of percentage menstruating at each age, are subjected to probit or logit analysis to give the mean age of menarche (inquiring of girls in a school what age they were when they first menstruated leads not only to errors of recollection, but to an important bias if there remain any girls who have not yet menstruated). The only group which nowadays has menarche as late as many European rural and poorly off communities a hundred years ago is the Buni of New Guinea.

^d Longitudinal data (Demings figure may represent a biased selection of the Denver longitudinal sample, and be lower than is representative)

There is at present little sign that the trend shown in Fig. 43 has stopped. It seems likely that the biological limit for European populations may be represented by an average of around 12¾ years. There is, of course, no reason a priori to suppose that rapid growing up is in itself biologically, psychologically, or sociologically either advantageous or disadvantageous.

The causes of the trend (or acceleration of growth as it is sometimes called) are probably multiple. Certainly better nutrition is a major one, and perhaps in particular more protein and calories in early infancy. A lessening of disease may also have contributed. Some authors have supposed that the increased psychosexual stimulation consequent on mod-

ern urban living has contributed, but there is no positive evidence for this. Girls in single-sex schools have menarche at exactly the same age as girls in coeducational schools, but whether this is a fair test of differences in psychosexual stimulation is hard to say.

The trend toward increased height in adults does not necessarily have the same causes. Probably better nutrition has contributed to it also, but there may in addition be a genetical explanation. If some degree of dominance occurs in genes increasing stature, then increased outbreeding, producing more heterozygotes, would increase the height of a population. There is increasing evidence that such dominance does in fact occur. As for outbreeding, that has been in-

creasing steadily since the invention of the bicycle

ACKNOWLEDGMENTS

I wish to thank Mr R H Whitehouse, Dr S Hammar, Mr H Goldstein, and Mr

P C R Hughes for making measurements and calculations on which a number of the figures are based, Dr W A Marshall for a most helpful reading of the manuscript, and the Nuffield Foundation and the Medical Research Council for financial support

4 *Physiological Development*

DOROTHY H. EICHORN

Regardless of age, size, or complexity, all organisms perform the same basic physiological functions to remain alive. Each obtains from food the materials for repair or replacement of cells and energy for all its activities. Release of energy from nutrients requires oxidation. For the control of both oxidative and synthetic reactions secretions such as enzymes must be produced. Waste products accumulate from all metabolic reactions, and, as is known from chemical laws of mass action, will slow and eventually block these reactions, unless the organism has some means of excretion. If nutrients and oxygen are to reach all cells and their parts and wastes to be removed from them, circulation is needed. To respond to changes in the internal and external environments, the organism must be irritable. Not only the avoidance of danger and acquisition of food, but also the mechanics of digestion, respiration, and circulation involve movement.

Whether an organism is growing or not, it carries on all these activities. For growth to occur, some must be intensified, but the processes that fulfill the replacement function also underlie development. Only the creation of new individuals by organisms that reproduce sexually adds any function beyond those necessary for the existence and reproduction of single cells.

Viewed structurally, there is great diversity among species, and even within the same organism during the course of development, in the organs that support any given process, but the essential functions are the same in plant and animal, unicellular or multicellular, at all stages. If the student focuses on function, he will find the facts of human

physiological development easier to assimilate. The details that provide difficulty in understanding arise because (1) the human prenatal and postnatal environments are strikingly different, and each requires special adaptations, (2) complex organisms inherit many of their basic mechanisms from earlier, simpler forms, and have at least temporarily some structures characteristic of these simpler forms, and (3) the larger the organism becomes, the more remote are most of its cells from environmental supports, so specialized cells and organ systems, each with multiple controls, must be developed and integrated.

Many students of behavior think of its morphologic and physiologic bases in terms of only two or three systems—the neural, the muscular, and parts of the endocrine—and of these only in relation to the external environment—the processes of perceiving and responding to external stimuli. Yet most cells of the human body are carefully shielded from the general external environment. Those that are not completely insulated can exist only because they are also in a well-regulated internal environment, one that is essentially the same for all cells. Every functional system contributes to the compensatory mechanisms that keep the fluids surrounding each cell relatively constant in temperature, acid-base balance, concentration of nutrients and ions, osmotic pressure (pressure resulting in diffusion between solutions of different concentrations), and other characteristics. In the preceding chapter and several of the succeeding ones, the development of neuromuscular functions that mediate interactions with the external environment are described. Here

the emphasis will be on the processes that permit life to continue and development to proceed in the face of change in both the organism and its external environment

As is true in the study of behavior, the development of functions can be dealt with in either of two ways. The level of development of all organic activities can be considered at a number of successive ages, or each different function can be traced individually throughout the course of its development. The first method has the advantage of calling attention to the fact that all systems are interrelated but the rate of development or decline is not the same for all. However, one tends to lose sight of the pattern of changes in particular functions. Further, as the organism becomes more complex, so do the interactions within a single system. To present a coherent picture of the intricacies of all activities simultaneously is virtually impossible except during the earliest stages of gestation when the organism is very small and relatively simple in structure. Therefore, after an overview of beginning phases, major functions will be approached separately.

EMBRYONIC DEVELOPMENT AND PLACENTATION

Nowhere are the principles outlined in the first two introductory paragraphs better illustrated than in the succession of means by which the human being secures food and oxygen and eliminates its wastes. Unlike the ova of lower vertebrates, those of most mammals have almost no yolk. Rather than drawing on a stored supply of food, the mammalian embryo quickly establishes a parasitic relationship with the mother. In the human this process is particularly elided, for the first phases of differentiation of the embryo itself are also relatively more rapid than in other mammals, imposing increased demands for food, oxygen, and elimination very early in gestation. Throughout most of the many months that the intricate digestive, respiratory, and excretory structures necessary for postnatal function are developing, the placenta acts as intestinal wall, lung, and kidney (and serves storage, endocrine, and barrier functions as well). About three weeks are required, however, for the human embryo to build up a placenta and vascular connec-

tions with it. Meanwhile, its cells carry on their essential metabolic activities through direct absorption from, and excretion into, the surrounding environment.

The first week or fortnight after conception is termed the ovular phase or period of the zygote, the second or third to the eighth week is called the embryonic period or period of organogenesis, and the remainder of gestation is the fetal period. Before it burrows into the lining of the uterus, the zygote spends about three or four days traversing the fallopian tube and another three or four free in the uterine cavity. During this time the ovum, which is the largest human cell, subdivides into a hollow ball of ordinary-sized cells, the blastocyst. It contains fluid rather than the yolk found in the blastocyst of lower vertebrates. At one end is the inner cell mass from which the embryo develops. Because very little growth occurs—the blastocyst is only a little larger than the original ovum—little food is needed, but the human zygote may utilize secretions from the fallopian tube.

While the fertilized ovum is still in the tube, the trophoblast, a layer of cells not part of the embryo proper, probably has begun to differentiate and cover the blastocyst. At least in human embryos recovered at seven or eight days after conception, trophoblast is already quite thick over the area that has started to invade the uterine wall. Trophoblast cells secrete fluid into the cavity of the blastocyst, phagocytize nutrient materials, and adhere to and destroy some of the endometrium (the mucous membrane lining the uterus). Once implantation has begun the embryo has available not only glycogen-containing secretions from uterine glands, but also cellular constituents and fluids from endometrial cells and blood vessels eroded by the trophoblast. Trophoblastic or histotrophic nutrition is characteristic of the second to fourth weeks, that is, from the initiation of implantation to the establishment of placental exchange, but may continue concomitantly with the latter for several more weeks.

A more effective method for securing food and oxygen than phagocytosis and direct absorption is urgently needed, for by the third week the embryo is growing rapidly. When the developing organism begins to enter the uterine lining between the seventh and ninth

day it is already more than a simple blastocyst. The inner cell mass is now an embryonic disc with a definite layer of entoderm and a plate of potential ectodermal and mesodermal cells, the trophoblast consists of two layers—a thin generative layer of cytotrophoblast and a thick outer syncytium of cells that have lost their boundaries, and another extraembryonic membrane, the amnion, is separating from the embryo. The fluid-filled amnion helps to prevent adhesions and mechanical injury. Later in gestation the fetus may swallow amniotic fluid and excrete fluid into the amnion.

Differentiation, particularly of the extraembryonic structures and the embryonic cardiovascular system, is prodigious during the second and third weeks. Textbooks on developmental psychology usually stress the precocity of neural development but do not mention the accelerated rate of differentiation of the intraembryonic and placental circulatory systems. Near the end of the second week a third extraembryonic structure, the yolk sac, is distinguishable, and within a few days it has blood vessels. The yolk sac can be considered vestigial only in terms of its original function, for it is the site of the first blood formation in the human being and remains for some weeks a source of blood cells. The proliferating trophoblast acquires a core of mesoderm and is called trophoderm or serosa. Early in the third week both the body stalk, a narrow strip of mesoderm connecting the embryo and the trophoderm, and the allantois, an extraembryonic membrane which soon coalesces with the trophoderm to form the chorion, or fetal side of the placenta, can be seen. The clusters of trophoderm are organizing into bushy tufts or villi and developing lacunae that unite to become the intervillous space into which blood from eroded maternal vessels flow. As mesoderm and blood vessels differentiate from allantoic tissue, they penetrate the villous branches, transforming them, by the end of the third week, into true chorionic villi.

Simultaneous with these elaborations of the extraembryonic structures is the differentiation of the embryonic cardiovascular system. During the third week the paired strands of cells that constitute the primordia of the heart appear, one on each side of the gut. They are hollowed out, brought together,

and fused into a simple tubular heart. Meanwhile the primary blood vessels arise in much the same fashion. Cords of cells develop lumina (cavities), merge into small channels, and then enlarge. From the paired aortas thus formed branches are put out, among the largest of which are the arteries that extend from the dorsal aorta (running from the heart to the caudal end of the embryo) to the yolk sac and to the chorion. The intraembryonic portions of the former are the omphalomesenteric arteries and their continuations in the yolk sac are the vitellines, but for convenience both are often called vitelline arteries. The arteries to the chorion are known as the allantoics in recognition of their destination—the vascular plexus derived from the allantois and now investing the trophoderm—or as the umbilical arteries, because they run through the body stalk, the forerunner of the umbilical cord. Paired veins develop similarly but slightly later, and, again, those returning to the embryo from the yolk sac and from the chorion are very prominent.

The heart begins to beat about the end of the third week, but its early contractions are autonomous, innervation is not completed for several weeks. Fluid is present in the venous circuits to the heart, and immediately before circulation is initiated blood corpuscles from the yolk sac are added. When the contractions of the heart become sufficiently strong, these corpuscles move with each beat. As soon as networks of small channels differentiate to connect arteries and veins, the intraembryonic, yolk sac, and chorionic or placental circulations begin. This is probably early in the fourth week but may be late in the third. The course and dynamics of the fetal and postnatal circulations are described in the section on the cardiovascular system. Several important facts about the prenatal circulation and placental structure and physiology should be noted here, however.

First, all three vascular arcs undergo many further transformations. The straight tubular heart bends and twists and develops by the end of the second month into a four-chambered structure, differing in small but important respects from the adult heart. Metabolic need is the primary determinant of the course and size of blood vessels, but some temporary routes represent recapitulations of

phylogeny Moreover, vascular channels may be altered because other structures interfere, as illustrated by the interruption of the umbilical veins by the rapidly enlarging embryonic liver Channels develop connecting these veins with the vascular network in the liver, so that eventually all blood returns from the placenta to the heart through the liver Further, the umbilical veins coalesce in the umbilical cord, so that only the left umbilical vein carries blood from the placenta to the liver, the right simply drains the body wall and flows into the left Because tissue needs to be well provided with blood only while metabolically active, some channels develop extensively and then regress For example, the yolk sac and its vessels are of large size for several weeks, but shrink and become nonfunctional after the fifth or sixth week Within the embryo, all new tissue must be vascularized, and, of course, the process continues postnatally in all growing tissue, but the more active organs always are the better supplied Thus during gestation the placental circulation is much greater than that to the lungs After birth, however, the reverse is true, the pulmonary circuit being large and the umbilical vein remaining only as ligaments and the umbilical arteries as minor vessels to tissue between their original branching point and the umbilicus and as fibroid cords

Not only purely vascular changes occur in the placenta and accessory structures Not until the fifth week does a true umbilical cord come into being As mentioned previously, the body stalk originates from extra-embryonic mesoderm After the allantoic or umbilical arteries and veins appear they push out to the chorion through this rapidly growing stalk, and the allantois is also embodied within it At the edge of the umbilicus the amnion and the body wall of the embryo are continuous, so the umbilical ring is the juncture of embryonic and extraembryonic tissue Both the stalk of the yolk sac and the body stalk with its incorporated blood vessels and allantois pass through this open ring, which becomes progressively smaller During the fifth week the amnion envelops these stalks and forces them together, forming the umbilical cord Elongation of the cord continues to a final length somewhat greater than that of the fetus.

In contrast to the regression of the yolk sac, growth and modifications of both the maternal and fetal sides of the placenta persist throughout gestation Although the size of the placenta relative to that of the uterus is greatest at the fifth month, growth is maintained thereafter At least as important for the function of the placenta as its size are the alterations in its structure Whereas the early invasive action of the trophoblast is predominant, the villi have comparatively few short branches but cover the entire chorionic surface Those not in the region of implantation later atrophy, while the villi in the discoid placental area elaborate Not only do the branches increase in size and complexity, they also become more organized in external and internal structure Instead of many hundreds of villous clumps covered with sprawling trophoblast, there are 15 or 16 treelike groupings called cotyledons separated by septa Within the spaces bounded by these septa the ends of the majority of villi lie unattached and surrounded by the blood that oozes from eroded maternal blood vessels The termini of some "anchoring villi," however, come into progressively closer contact with the endometrium Their trophoblast is lost, as is the outer lining of the uterus below them, so the connective tissue core of the villi adheres to the connective tissue of the uterus Less complete reduction of the trophoblastic covering of the free villi also occurs, the outer syncytial cells thinning markedly and almost all of the inner cytotrophoblast layer disappearing This attenuation of the epithelial covering of the free villi begins once the chorion is well established, that is, at about the end of the second month, but is more extensive during the last three months of gestation

To some extent these processes enhancing transfer of nutrients, gases, and wastes across the placenta are counteracted as gestation proceeds by the deposition of a fibroid substance which is probably an amalgamation of material from the maternal blood, the uterine lining, and the chorion (Arey, 1965, Patten, 1953) Certainly in abnormal circumstances interference with placental exchange has been observed (Nesbitt, 1966) In any event, the amount of tissue through which metabolic interchange must take place varies during prenatal existence although in prin-

ciple three cellular layers of the villi separate the fetal from the maternal blood—the endothelial lining of the capillaries, stroma or supporting tissue, and the syncytial layer of the trophoblast. For more detail about the histology of the placenta and the development of the fetus and its accessory structures the student should consult specialized articles and volumes such as those of Amoroso (1961), Aherne and Dunnill (1966), Arey (1965), Patten (1953), and Villee (1960).

Because the normality and rate of prenatal development are highly dependent upon the nature and amount of substances passing the placenta, the subject of placental permeability is of great practical as well as theoretical significance (Benirschke, 1965; Dancis, 1965; Hepner and Bowen, 1960; Warkany, Monroe, and Southerland, 1961; Wigglesworth, 1966; Wilson, 1964). Summaries of early research are included in the classic works of Needham (1931) and Windle (1940). More recent reviews can be found in Adamson (1965), Hagerman and Villee (1960), Page (1960), Villee (1960), and Widdas (1961).

Permeability is neither qualitatively nor quantitatively fixed from species to species, cell to cell, or moment to moment. Instead it fluctuates with substance, environmental conditions such as temperature and oxygen supply, level of metabolic activity, and characteristics of the membrane. The supply of nutrients in the maternal blood often exceeds current fetal need, particularly early in gestation. In the human and many other animals, nutrients are then stored, probably selectively, by the fetal placenta for later release. At a given point in time, therefore, the amount of a nutrient transferred may be modified by the reserve accumulated as well as by the concentration gradient between maternal and villous blood. Special mechanisms exist whereby molecules too large to diffuse through the pores of a membrane (e.g., glucose, amino acids, and vitamins) or small molecules indiffusible for other reasons (such as the ions of most electrolytes) can be transferred. If a membrane is damaged, leakage may also be a factor. As has been demonstrated in the rare instances in which red blood cells have passed the placenta (Page, 1960), even large particles can

leak through damaged membranes if the hydrostatic pressure is sufficiently great.

The surface area and thickness of a membrane are important factors in the regulation of transport across it. In general, placental size increases and the density of the placental barrier decreases throughout gestation. There are, however, differences among species and developmental variations within species in the size of the placenta relative to the fetus and in the number and thickness of the cellular layers separating fetal and maternal blood. Size has been estimated in terms of surface area, volume, and weight. These measures are intercorrelated, but none is an exact guide to functional capacity. Neither weight nor volume directly reflects the absorptive area, and not all the surface area is involved in metabolic interchange. Some of it, such as the septa, chorionic plate, and fibrinoid areas, lacks capillaries narrowly separated from maternal blood.

Early in gestation the weight of the placenta increases faster than that of the fetus, but later the reverse is true. For each species there is a time at which the placental fetal weight ratio is maximal and one at which the weights become equal. Thereafter, fetal weight is progressively greater. In some species placental growth ceases before the end of gestation, but in monkey and man the weight of the placenta increases to the normal time of delivery.

At term the human placenta is about 14% of fetal weight. Its surface area has been estimated to range from about 7 square meters (Dodds, 1922) to 14.7 square meters, or about 160 square feet (Dees-Mattingly, 1936; Wilkin, 1958). Recently Aherne and Dunnill (1966), using improved methods, estimated the surface area of the intervillous space and villi (exclusive of microvilli) to be 11 square meters at term, and the villous area which contained capillaries close to the surface to increase from 0.4 square meters at 28 weeks to 1.8 at full term. That any of these figures is considerable is indicated by the fact that the surface area of the skin of a full-term newborn infant is about 0.22 square meters and that of the "standard 70 kilogram adult male" about 1.74.

In all likelihood the absorptive area of a normal placenta throughout most or all of

the time the fetus is dependent upon it for metabolic interchange is not only adequate to meet fetal needs but also provides a margin of safety. This margin may narrow near the end of gestation. Fetal weight is significantly correlated with placental weight in many species, including man (Adair and Thelander, 1925; Calkins, 1937; McKeown and Record, 1953; Aherne, 1966; Winick, Coscia, and Noble, 1967), but variations in both weights, independent of placental size and gestational age, have been observed to develop between single and multiple births very late in gestation in both man (McKeown and Record, 1953) and the guinea pig (Ibsen, 1928).

Grouping placentae by the number of layers of maternal and fetal tissue between the two bloods yields five classes

- 1 Epitheliochorial (maternal endothelium, connective tissue, and epithelium, and fetal chorion, mesenchyme, and endothelium)
- 2 Syndesmochorial (lacking maternal epithelium)
- 3 Endotheliochorial (lacking both maternal epithelium and connective tissue)
- 4 Hemochorial (only fetal endothelium and chorion—trophoblast and stroma)
- 5 Hemoendothelial (only fetal endothelium)

Pigs and horses fall in the first classification, sheep and cattle in the second, the dog and cat in the third, monkeys and man in the fourth, and the rat, rabbit, and guinea pig in the fifth.

Across species and developmentally within species the width of the placental barrier is negatively correlated with permeability. Yet the correlation is far from perfect, and a specific substance may pass a dense placenta but not a simpler one. For example, in the rat, which has both a hemoendothelial placenta and a simultaneously functional thicker yolk sac placenta, the dye toluidin blue passes the latter more easily than the former (Windle, 1940). A striking illustration of developmental changes is found in the rabbit. During a gestation period of about $4\frac{1}{2}$ weeks its placenta is reduced from syndesmochorial to hemoendothelial (Windle, 1940; Amoroso, 1952).

Morphological variations in placentae have

an important bearing upon the validity of our knowledge about human prenatal function. Still more frequently than is the case under postnatal circumstances, ethical and practical considerations contraindicate experimentation with human beings. Unfortunately, generalization of observations or experimental results from one species to another or of measurements taken at one point in time on a fetus to other periods is even more hazardous before birth than after. To all the usual factors restricting the comparability of species must be added not only structural variations of the placenta, but also length of gestation, degree of maturity at analogous stages (e.g., birth), physiological characteristics of the placenta (such as pressure and concentration gradients, oxygen supply, and storage, enzymatic and other metabolic activities), and the kind and extent of fetal and maternal adaptations to the conditions of gestation.

Selection of an appropriate species for studying a particular function is difficult because one that resembles man more closely in size or the manner in which the activity is carried out may differ markedly in gestation period or placental morphology and function. For several reasons the sheep and rabbit are subjects of choice for investigations of prenatal respiration, as are the rat and guinea pig for nutritional studies. However, the sheep's placenta is less advanced than man's and its gestation period is only about half as long. Some peculiarities of the placenta in the rabbit and rat have been detailed earlier, both have short gestations.

Normal prenatal development requires physiologic adjustments of the mother as well as of the fetus, and the human being is a prime example of a species in which modifications of the maternal physiology are extensive. Periodic changes in the secretion of gonadal hormones condition the uterus for implantation, increasing the size of uterine glands and the amount of fluid and glycogen they contain. If conception occurs, the production of many hormones by the pituitary, thyroid, and adrenocortical glands eventually rises. Probably in response to hormonal stimulation, blood and tissue fluid volumes become greater.

As gestation proceeds, more blood flows through the uterus (Assali, Douglass, Baird,

Nicholson and Suyemoto, 1953, Huckabee, 1962, Metcalfe, Romney, Ramsey, Reid, and Burwell, 1955) and the total peripheral resistance of the maternal circulatory system drops, increasing the venous return to her heart and hence her cardiac output. Under normal circumstances the mother's cardiac output rises gradually during the first 7 months of pregnancy to 30 to 50% above the nongravid level and then drops somewhat during the last 8 weeks (Bader, Bader, Rose and Braunwald, 1955, Burwell and Metcalfe, 1958, Hamilton, 1949). Oxygen consumption rises approximately 30% as the time for delivery is approached. At the same time the expanding uterus pushes the abdomen against the diaphragm, reducing the respiratory excursion. To adjust to this handicap and to the increased demand for oxygen, the rate and depth of respiration increase.

The methods used in prenatal experiments also limit the conclusions that can be drawn from them. Prematurely delivered fetuses are obviously not functioning in a normal prenatal environment, and spontaneous prematurity is presumptive evidence of abnormality in mother, fetus, placenta, or some combination of the three. Even when the placenta is left attached and intact and sufficient time is allowed for recovery from anesthesia and possible surgical shock, any surgical intervention alters the normal physiologic condition of mother, fetus, and placenta. Anesthesia is essential for all but the most minor surgery, but anesthetic procedures vary in the degree to which they prevent shock as well as in the complications they may induce in fetus and mother. Windle's summary (1940, p. 10) of the dilemma posed by prenatal research still applies:

The problems involved in most investigations in physiology of the fetus are complicated because one is dealing with two organisms maintaining mutual although precarious relationship to one another. It is true that the fetus cannot be studied under physiologic conditions when the health of the mother is jeopardized, but on the other hand the best of conditions in the mother do not insure that behavior of the extracted fetuses will always be normal.

Although improved techniques devised since

that statement was written help to minimize the physiologic disturbances created by experimental manipulations, the reservations outlined here should be kept in mind when evaluating any research on prenatal function.

HEMATOLOGY

Most cells of a complex multicellular organism are remote not only from the external environment but also from the organism's specialized tissues for nutrition, excretion, and internal secretion (e.g., of hormones). If the essential needs of each cell are to be met and its environment kept relatively constant, a link between all cells and the sources of food, oxygen, and internal secretions and the organs of elimination—kidneys, intestine, lungs, and skin—is necessary. This function is fulfilled by the body fluids—blood, interstitial fluid, and lymph.

As the primary vehicle of distribution, blood plays a role in almost every bodily activity. However, it remains in a system of closed vessels and is not in direct contact with cells (except those lining the walls of the blood vessels) so a means of interchange between blood and cells is needed. The medium of exchange is provided by interstitial fluid, which occupies the space around cells and is derived from the plasma of blood, largely through diffusion and filtration. Lymph is the fluid that drains from the intercellular spaces into the system of lymphatic vessels and thence back into the blood via lymphatic ducts emptying into the venous circulation.

Blood is composed of a complex fluid, plasma, which contains a large number of dissolved materials and in which are suspended the formed elements of blood—erythrocytes (red corpuscles), leukocytes (white cells), and thrombocytes (platelets). About 90% of plasma is water. Among the substances dissolved within it are the major blood proteins, digested forms of nutrients, wastes, gases, electrolytes, hormones, and enzymes. The proteins contribute to acid-base regulation, nutrition, coagulation, and immunological responses and to such functional characteristics of plasma as its viscosity, specific gravity, and osmotic pressure. In addition to transporting oxygen, erythrocytes are important in the maintenance of the acid-base

balance, viscosity, and specific gravity of the blood, and then membranes contain a number of agglutinogens, the determinants of blood types

Most white cells (leukocytes) are involved in defense against foreign matter such as bacteria and allergens. Platelets participate in several aspects of blood clotting

Sites of Hematopoiesis Hematopoiesis (hemopoiesis) is the general term for blood cell formation. Erythropoiesis, leukopoiesis, and thrombopoiesis refer to the formation of red cells, white cells, and platelets, respectively. Under normal circumstances all the formed elements of adult blood, except the majority of lymphocytes and monocytes (two types of white cells), are produced in the bone marrow. The source of monocytes is not definitely known, but lymphocytes and probably the monocytes are formed in lymphoid tissue in many parts of the body, for example, the lymph nodes, spleen, tonsils, thymus, liver, gastrointestinal tract, and bone marrow

Despite the fact that bone marrow appears during the sixth prenatal week, blood cell formation does not begin there until almost mid-gestation. Instead, the final stage of hematopoiesis, known as the myeloid (bone marrow) period, is preceded by two successive and overlapping stages during which other tissues are the primary centers of blood formation

In the embryo, blood cells and blood vessels arise from mesenchyme, the embryonic connective tissue. The earliest sites of hematopoiesis are the "blood islands" in the yolk sac (Bloom and Bartelmez, 1940; Wintrobe, 1961), and these islands probably also secrete plasma. Although neither the time limits of this first stage, the mesoblastic period, nor of the succeeding stages can be stated exactly, blood islands and primitive blood cells are known to be present early in the third week. Active hematopoiesis continues in the yolk sac to the sixth or seventh week and then declines rapidly. By the ninth week blood formation there is negligible

The second or hepatic (liver) period begins about the fourth or fifth week, and within a few more weeks the liver has replaced the yolk sac as the prime site of hematopoiesis (Gilmour, 1941; Wintrobe, 1961). At about the third month hemopoie-

sis also starts in the spleen. It is always slight relative to that in the liver; it reaches a maximum about the fourth month and then subsides but may continue to a slight degree throughout the remainder of gestation. A brief phase of hematopoiesis also occurs in the thymus during the hepatic period

Between the fourth and fifth months hematopoiesis is initiated in the bone marrow and lymph nodes. Blood cell formation is much greater in the bone marrow and accelerates, whereas production in the lymph nodes rises for only a brief time and then stays steady to term. Since hemopoiesis continues in the liver until two or three weeks after birth, although at a decelerating rate after the fifth month, there is considerable overlap between the hepatic and myeloid periods

As noted earlier, the bone marrow becomes the exclusive normal site of erythropoiesis, thrombopoiesis, and the formation of most white cells within a few weeks after birth. However, the liver and spleen and perhaps other tissues retain their potential for hematopoiesis throughout infancy and early childhood and thus serve as emergency sources in times of crisis. Formation of blood cells in these sites is called extramedullary hematopoiesis

Until a child is about 5 years old, the demand for blood cells is so great that red marrow fills all bones. Fat begins to appear in the marrow of long bones between the fifth and seventh year. With increasing age thereafter fat gradually replaces active marrow in the distal parts of the skeleton. By 18 or 20 years the centers of hematopoiesis are confined primarily to bones in the trunk—vertebrae, ribs, sternum, clavicles, and scapulae, and the innominate bones which make up the greater part of the pelvis—but some blood cell formation continues in the skull and the proximal epiphyses of the femur and humerus (Custer, 1949). The inactive, fatty areas of bone replace extramedullary centers as the reservoir for additional hematopoiesis during stress

Erythrocytes All the blood cells of the adult go through a series of transformations before they are released into the circulation, and some further developments may occur there. The normal stages of erythropoiesis are, in chronological order: pronormoblast (proerythroblast), basophilic, polychromatic,

and orthochromatic normoblast (or early, intermediate, and late erythroblast), reticulocyte, erythrocyte. Sometimes the term erythroblast is used to mean all nucleated red cells, regardless of stage or normality. All the forms listed above are nucleated except reticulocytes and erythrocytes, the two types of red cell normally found in the circulating adult blood. The more immature forms in the series are rather large, but as maturation proceeds through successive cell divisions, the red cells become progressively smaller. Before a red cell enters the adult circulation it normally extrudes its nucleus. A network of material with an affinity for basic dyes remains, so the cell at this stage is called a reticulocyte. After two to five days in the circulation the network is lost, and the cell is known as an erythrocyte.

The basic stimulus to erythropoiesis is a reduction in the oxygen level in bone marrow, whether this results from anemia (deficiency in the quality or quantity of red cells), hypoxia (low oxygen content of inspired air), or some other cause. However, the response is mediated by erythropoietin, a hormone secreted into the blood, probably by the kidneys.

Embedded in the colorless, spongy stroma, or framework, filling the interior of the erythrocyte is the red, oxygen-carrying pigment, hemoglobin. Every molecule of hemoglobin consists of four subunits, each of which has a heme portion containing iron, in conjugation with a polypeptide. Two of the subunits have one type of polypeptide, the other two have the second type. The polypeptides in the predominant form of adult hemoglobin are the alpha and beta chains. Both contain 19 different amino acids, but the alpha has 141 amino acid units and the beta has 146. Collectively, the polypeptides make up the globin fraction of the hemoglobin molecule. There is only a low to moderate correlation between the total amount of hemoglobin in the blood and the number of erythrocytes. When the components of hemoglobin are deficient, red cells mature without a normal complement of hemoglobin.

Red cells wear out after circulating for about 120 days. Deteriorated cells are broken down in the reticuloendothelial system, a special sort of connective tissue. Globin and heme are split off, with the former re-

turning to the amino acid pool of the body. Heme is transformed through several steps to insoluble bilirubin, a yellow pigment. Bilirubin is released into the circulation and carried to the liver, where it is converted into soluble forms and excreted in the bile. If this process fails, or excessive destruction of red cells occurs, the result is hyperbilirubinemia, or jaundice. There has been considerable controversy about the cause of icterus neonatorum, a form of jaundice common among neonates.

Much of the iron removed from the hemoglobin molecule when erythrocytes are destroyed is returned to the bone marrow to be reused in the formation of new hemoglobin. Unless the portion excreted is replaced by dietary intake, iron deficiency anemia ensues. Among other causes of insufficient or abnormal erythropoiesis are protein lack, vitamin deficiencies (particularly of the B vitamins), low levels of glucocorticoids (a class of adrenal hormones), or of thyroid or pituitary hormones, and genetic defects.

In general, the younger the individual, the more does the red blood cell picture present conditions that would be abnormal in the adult. This statement is qualified because some measures have curvilinear trends. The first characteristic to approximate adult levels—the proportion of immature cells in the circulation—shows only minor reversals. Release of nucleated cells into the circulation is indicative of pathology in adults, an elevated reticulocyte count is the normal sign of active red cell proliferation. Fetal blood, however, contains a large number of even less mature cells.

About the third week, when the first cells appear in the blood of the embryo, at least 99% are nucleated (Playfan, Wolfendale, and Kay, 1963). Further, they are large, primitive erythroblasts sometimes referred to as "first generation" or "provisional" erythroblasts. As these cells degenerate or are destroyed by phagocytes (cells that engulf and ingest other cells, microorganisms, and foreign matter), they are replaced by the second or "definitive" generation of smaller normoblasts (Bloom and Bartelmez, 1940). At 6 weeks most (92%) of the circulating red cells are still of the primitive type. The proportion drops to 53% by the end of the

second fetal month, and at the end of the fourth all of the red cell precursors are of the second generation. Concurrently, the number of very immature forms (erythroblasts and normoblasts) reaching the circulation decreases, while the more mature forms, at first almost entirely reticulocytes, increase. Only 3% (Thomas and Yoffey, 1962) to 8% (Wintrobe, 1961) of circulating red cells are nucleated at 10 to 12 weeks. By mid-gestation the proportion is less than 1% and remains at this level until delivery (Anderson, 1941; Gilmour, 1941).

Reticulocytes rather than nucleated cells are the predominant form of red corpuscle in the third fetal month. In turn, they are replaced by erythrocytes. This process is somewhat slower, especially after the first half of gestation, than was the decline of erythroblasts and normoblasts. Between the third and sixth months reticulocytes decrease from 90% of circulating red cells to 15-30% (Windle, 1941). According to Seip (1955), the proportion declines almost linearly from about 16% at 22 weeks to 4-6% at term. These figures are consistent with those reported in most previous and subsequent studies and are significantly higher than the normal adult range of 0.2 to 2.0% (McDonald, Dodd, and Cruickshank, 1965) or 0.5 to 1.5% (Smith, 1966).

Many other characteristics of red cells, for example, their size and total number, have a similar age curve—that is, rapid development during the first half of gestation and a slower, steadier rate of change thereafter. Underlying this pattern is probably an interaction between the degree of maturity of blood-forming tissue and the demand for red cells. Some abatement of this demand is likely, because as gestation proceeds the increment in size during a given period of time becomes a progressively smaller fraction of the size at the beginning of the interval (Arey, 1965).

At birth and for several months thereafter many readjustments in the red cell picture take place. Unless one knows the meaning of the various indices used to assess the size and quantity of cells and the hemoglobin content of cells or whole blood, neither the prenatal trends nor the postnatal reversals can be adequately understood.

An absolute increase in the total numbers

of formed elements would be expected throughout development, for the larger the organism, the greater is the volume of blood required to supply its organs. By the same token, the total amount of hemoglobin should also increase. To allow for differences in size, both among and within age and sex groups, cell counts and hemoglobin content are stated in relative terms.

Total counts of red cells (RBC), platelets, and white cells (WBC) of each category of the latter are given as the number of million cells per cubic millimeter (cu mm or mm^3) of blood. A supplementary measure for red cells is the hematocrit (HCT), or packed cell volume (PCV), which expresses the percentage of the volume of a given amount of blood that is occupied by red cells. The hematocrit is not a substitute for red cell count, because the same volume could be made up of a large number of small cells or a smaller number of larger cells. Among the measures of cell size are diameter, thickness, and volume. These may be measured directly, but estimates are sometimes used. For example, the mean corpuscular volume (MCV) is calculated by dividing the volume of packed red cells per 1000 milliliters (ml) of blood by the red cell count in millions per cubic millimeter, yielding a quotient in cubic microns ($\text{cu } \mu$).

In lieu of the older and less accurate color indices (the color of a blood sample is matched with one of a set of standards), ratios of the hemoglobin content of blood to the red cell count or the volume of packed red cells are now favored for the assessment of the hemoglobin content of red cells. The mean corpuscular hemoglobin (MCH) is a measure of the weight, in micromicrograms ($\mu\mu\text{G}$ or $\mu\mu\text{Gm}$), of the hemoglobin in the average red cell. It is derived by dividing the number of grams of hemoglobin per 1000 ml of blood by the red cell count in millions per cubic millimeter. By contrast, the mean corpuscular hemoglobin concentration (MCHC) is an estimate of the concentration of hemoglobin in the average red cell, that is, the ratio of the weight of hemoglobin to the volume in which it is contained. This quotient is a percentage, obtained by multiplying the number of grams of hemoglobin per 100 ml of blood by 100 and dividing the result by the volume of packed red cells in milliliters per

100 ml of blood If the mean corpuscular hemoglobin does not change in proportion to the mean corpuscular volume, the mean corpuscular hemoglobin concentration will deviate from normal, for it is the ratio of MCH to MCV This fact is particularly useful in the diagnosis of anemias Cell volume and the weight of hemoglobin per cell change in parallel in most anemias, so the MCHC is constant In certain anemias, however, the decrement in hemoglobin is greater than that in cell size, and the MCHC becomes subnormal The so-called "physiological anemia" of infancy, to be discussed shortly, is of the former type

The increment in number of red cells per unit volume of blood is rapid until mid-gestation when production slows (Singer, Chernoff, and Singer, 1951, Thomas and Yoffey, 1962, Walker and Turnbull, 1953, White and Beaven, 1959, Wintrobe and Shumacher, 1936) Thomas and Yoffey (1962) report a secondary rise in the third trimester More regular and gradual increases in packed cell volume and amount of hemoglobin per 100 ml of blood result from the relationships between curves for cell volume and cell count in the first case and mean corpuscular hemoglobin and cell count in the second (Wintrobe, 1961) Because mean corpuscular volume and mean corpuscular hemoglobin decrease at comparable rates, the mean corpuscular hemoglobin concentration stays at about the same level throughout gestation (Windle, 1941, Wintrobe and Shumacher, 1936)

Of great concern to hematologists, embryologists, and pediatricians are the qualitative differences between fetal and adult hemoglobin The heme fraction and the pair of alpha chains are identical in both hemoglobins, but instead of the pair of beta chains of adult hemoglobin (Hb-A), fetal hemoglobin (Hb-F) has a pair of gamma chains (Schroeder, Shelton, Shelton, Cormick, and Jones, 1963, White and Beaven, 1959) Although beta and gamma chains contain the same number of amino acids, the composition differs Fetal and adult hemoglobin differ in many physical and chemical properties, the most important of which physiologically is the greater oxygen affinity of Hb-F (see the section on Respiration) To date there is no conclusive evidence that the dif-

ference in oxygen affinity between fetal and adult blood actually arises from the beta and gamma chains rather than from other properties of the red cells or their environment

The values reported for fetal hemoglobin at different ages vary considerably from study to study In part the lack of consistency stems from the use of methods of assessment that differ in sensitivity and variability Further, fetal red cells contain small amounts of adult hemoglobin and two other minor hemoglobins The latter two constitute about 10% of the total hemoglobin and are included by some investigators in their figures, that is, they differentiate only between Hb-A and all other hemoglobin Adult blood also has two minor components—Hb-A₂ and very small amounts (0.5–1%) of Hb-F

During gestation very little shift in the proportions of fetal and adult hemoglobin is observed About 95% of the hemoglobin at 8 to 20 weeks is Hb-F, although small amounts of adult hemoglobin can be detected (Fraser and Rape, 1962, Walker and Turnbull, 1955, Zipursky, 1966) Most investigators report fetal hemoglobin values of about 90% at 34–36 weeks (Beaven, Ellis, and White, 1960, Cook, Biodie, and Allen, 1957, Cottom, 1955, Schulman, Smith, and Stein, 1954) In fact, the 90–91% level seems to be a criterion of prematurity Infants born before 34–36 weeks have more than 90% Hb-F, whereas those born after this age have less than 90% A negative correlation between gestational age and proportion of Hb-F is established at this point, with a decline of 3–4% in Hb-F each week thereafter to term (Cook, Biodie, and Allen, 1957) The range of Hb-F content found at birth varies from 45–90%, with means of 70–85% (Abrahamov, Salzberger, and Bromberg, 1956, Armstrong, Schroeder, and Fenninger, 1963, Cook, Biodie, and Allen, 1957, Cottom, 1955, Schulman, Smith, and Stern, 1954, Singer, Chernoff, and Singer, 1951, Zipursky, 1966) However, the concentration varies from cell to cell, and over 90% of red cells in the blood of newborn infants contain some fetal hemoglobin (Zipursky, 1966)

Even less agreement exists on the rate of the postnatal decline in Hb-F Beaven, Ellis, and White (1960) report that after the fourth month no more than 10% of hemoglobin is of this type In the age range 6

months to 10 years less than 1% Hb-F was found in about two-thirds of their subjects. On the other hand, Chernoff and Singer (1952) found levels of 15% fetal hemoglobin at 1 year, 5% at 2, and less than 2% after 4 years.

The factors determining whether the hemoglobin manufactured will be predominantly of the fetal or adult type are not known. When fetal red cells are incubated under conditions of glucose deficiency or low oxygen, fetal hemoglobin is more likely to be formed (Allen and Jandl, 1960). Thus one hypothesis is that in the fetal environment, where glucose and oxygen are in relatively short supply, hemopoietic tissue somehow responds to such lack by producing fetal hemoglobin.

It is of some interest that the myoglobin (muscle hemoglobin) of fetuses and newborn infants is entirely of a fetal type, MbF. During the first six postnatal months MbF is completely replaced by adult myoglobin (Singer, Angelopoulos, and Ramot, 1955). As is true for fetal hemoglobin, the significance of this shift has not been determined.

Despite the slowing of erythropoiesis during the second half of gestation, the picture at delivery is one of hyperactive red cell formation. A temporary resurgence of nucleated red cells, both erythroblasts and normoblasts, occurs in many infants, particularly the premature (Smith, 1959). Within 24 hours an abrupt decline ensues, and by the end of the first week almost all the nucleated cells are gone. Some investigators (Findlay, 1946, Gaudner, Marks, and Roscoe, 1952, Wegelius, 1948) also report an increase in reticulocytes lasting from a few hours to 3 or 4 days. Seip (1955) found that the term level (4-6%) was maintained for 3 days, then dropped rapidly, reaching the adult range by the end of the seventh day. No sharp decrement is seen in Washburn's (1935) longitudinal data until the second to eighth week. However, those data show a brief increase between 6 and 10 weeks, followed by a second decline to adult values at about 4 months.

In addition, the erythrocytes of the newborn infant are larger and have a higher hemoglobin content than the adult's, and their numbers are as great or greater (Smith, 1959, Smith, 1966, Wintrobe, 1961, Wol-

man, 1957). Some investigations reveal a further rise in red cell count lasting from a few hours to several days (Findlay, 1946, Gaudner, Marks, and Roscoe, 1952, Guest, Brown, and Wing, 1938, Wegelius, 1948). During the first day hemoglobin levels of subjects in these studies increased even more sharply, but they too began to drop after about the fourth day.

The brief perinatal burst of erythropoiesis is most frequently interpreted to be the result of relative anoxia late in gestation and/or during delivery. Evidence for anoxia during labor is much better than that for an increase in oxygen deprivation as term approaches (James and Adamsons, 1964, Nesbitt, 1966, Smith, 1959, Walker and Turnbull, 1959). Moreover, the red cell and hemoglobin values available in the literature, particularly for neonates, should not be accepted uncritically, for a number of methodological, environmental, and genetic factors influence these measures.

One important variable is the source of the blood sample. Among adults hematocrits determined on venous blood are slightly higher than those done on arterial blood, while samples from peripheral or small vessels yield hematocrits as high as those from larger vessels only when the microhematocrit is used (McGovern, Jones, and Stenberg, 1955). For about the first postnatal week, however, simultaneous capillary and venous determinations show the former to be higher (DeMaish, Alt, and Windle, 1948, Gatti, 1967, Mollison, Veall, and Cutbush, 1950, Mugrage and Andresen, 1936, Newman and Gross, 1967, Oettinger and Mills, 1949, Oh and Lind, 1966). The greater concentration of capillary blood probably comes about because the relatively inactive peripheral circulation allows more time for water to diffuse out of the capillaries. Smith (1959) collated red cell counts and hemoglobin levels from many studies on the basis of whether the blood was obtained from capillaries, veins, or the umbilical cord. In addition to reflecting the capillary-venous difference, his tables suggest that measures made on cord blood are lower than those taken on venous blood. Since simultaneous comparisons of cord and venous blood have not been made, one cannot be sure whether this difference

represents an age trend or a concentration gradient

Although the very high values for erythrocytes and hemoglobin frequently cited as characteristic of the newborn are based on capillary samples, dehydration from reduced water intake during the first few days of life may contribute to spuriously high values regardless of the source. Red cell and hemoglobin levels may actually begin to drop within the first day, with the decline being masked by a decrease in blood volume. Water loss is the primary factor in the early neonatal weight decrement, and transfer of water from the blood is one line of defense against cellular dehydration.

A related factor of considerable significance is the time at which the umbilical cord is clamped. Delayed clamping can result in the transfusion of large quantities of blood from the placenta to the infant (see blood volume, below). Transfusion per se would not influence counts or concentrations, but it has this effect because fluid adjustments occur in which water leaves the plasma and enters the intercellular spaces or tissues. In a recent review of the effect of time of clamping of the cord on a variety of functions, Moss and Monset-Couchard (1967) list 20 studies that included hematological evaluations. Despite variations in the source of blood samples and in the definition of early or late clamping, almost all studies showed late clamping to produce higher red cell and hemoglobin values. The differences ranged from about 0.5 to 1.5 million for erythrocyte counts, 11 to 15 cc per kilogram of body weight for red cell volume, 1 to 4 grams for hemoglobin levels, and 3 to 12% for hematocrit. On the other hand, infants whose cords are clamped early have higher reticulocyte counts (DeMaish, Alt, and Windle, 1948).

With distressing frequency investigators attempting to establish age standards have failed to control not only for the time of clamping of the cord but also for gestational age, multiple births, and anemias. The more premature the infant, the lower his blood values are likely to be and the greater will be the effect of placental transfusion at delivery, for red cell, iron, and hemoglobin levels increase with gestational age, whereas

the proportion of blood in the placenta decreases.

The fact that multiple births have an above average incidence of prematurity and non-deficiency anemia is not the only reason why their exclusion is desirable. More and more cases of placental transfusions between monozygotic twins, either prenatally or during delivery, are being discovered (see reviews in Corney and Aheine, 1965, Falkner, 1966, Rausen, Seiki, and Strauss, 1965). In this syndrome one twin is plethoric (has an excess volume of blood) while the other is anemic. The effects vary from mild to severe (Bennischke, 1958, Corney and Aheine, 1965, Naeye, 1963) and include abnormalities in growth, cardiovascular and renal function, vision, and hearing. It has been suggested that the rather common occurrence of non-deficiency anemia in one of a pair of twins when both have similar diets and growth rates may be instances in which the transfusion was not great and was not detected (Smith, 1966, Woodruff, 1958). The plethoric twin is usually but not always the larger (Falkner, Banik, and Westland, 1962, Kern, 1959, Littlewood, 1963, Valaes and Doxiadis, 1960) and is equally susceptible to severe disorders and death (Minkowski, 1962). Not all the deleterious effects are apparent at birth (Corney and Aheine, 1965), and the abnormalities and differences between twins in size and other variables often persist for years (Becker and Glass, 1963, Falkner, 1966, Herlitz, 1942). The fact that prenatal environmental factors may make monozygotic twins more dissimilar than are dizygotic twins or even unrelated individuals obviously has implications for developmental research far exceeding the relatively minor confounding of hematological norms that results from including subjects whose blood values are not normal.

Although anemia is basically an abnormally low level of hemoglobin in the blood, it can arise because the hemoglobin content of all cells is reduced or because the number of red cells is insufficient. These states, in turn, stem from deficient or defective red cell formation, excessive destruction of red cells, or a combination thereof. Among the conditions that produce anemic newborns are bleeding from the fetus into the mother through a damaged placenta, blood loss from

the placenta itself during delivery, a variety of genetic defects, and fetal-maternal blood group incompatibilities, of which the best known is the instance in which an Rh-negative mother carries an Rh-positive fetus. Descriptions of these and other disorders and a review of the literature on them can be found in Smith (1966). Dietary deficiencies and infections, which play a major role in anemias in older infants and children, are of comparatively little importance in neonates. Within a fairly wide range, maternal hemoglobin levels are not correlated with the production of hemoglobin by the fetus (Woodruff, 1956, 1958, 1961, Woodruff and Bridgeforth, 1953). However, if the mother's levels are very low, her offspring is much more likely to be anemic (Strauss, 1933, Woodruff and Bridgeforth, 1953). The incidence of neonatal anemia is also higher among premature and later-born infants and multiple births than in full-term and first-born infants and singletons, whose prenatal supply and storage of iron and other nutrients is better (Guest and Brown, 1957, Woodruff, 1958).

Whether or not a true increase in red cell and hemoglobin values takes place during the first few days after birth, there is no doubt that the normal infant enters postnatal life with every sign of active erythropoiesis and that within a week or so the rate of red cell formation is on the decline. As the high blood values at birth and possible increases during the first few days have been inferred to represent a response to decreasing oxygen tension, so the decreases which soon follow have been attributed to the removal of the stimulus to erythropoiesis by the more highly oxygenated postnatal environment. A time lag would be expected, because the primary response is by the erythropoietic tissue, and some days would be required for the change to be reflected in the circulation. Consonant with this interpretation is the fact that decreased or increased activity of the bone marrow, as appropriate, precedes the trends in blood values reported below (Smith, 1966).

The greatest variation in blood values "among infants or children apparently in states of good health and nutrition occur during the first three years of life" (Guest, Brown, and Lahey, 1957, p. 359). Other

authorities agree on this point as well as to the contention that "optimal" standards, that is, those based on well-nourished children, are preferable to those derived from a more representative sample, because the latter will include many anemic children (Moe, 1965, Whipple, 1966).

Despite the wide range from study to study in absolute values at given ages and discrepancies as to the age at which minimum levels are found, the general age trends are quite consistent (Albritton, 1952, Berry, Cowin, and Magee, 1952, Gardner, Marks, and Roscoe, 1952, Faxén, 1937, Guest and Brown, 1957, Guest, Brown, and Wing, 1938, Hawkins, Speck, and Leonard, 1954, Hoian, 1950, Leichsenring, Norris, and Halbert, 1952, Leichsenring, Norris, Lamison, and Halbert, 1955, Menitt and Davidson, 1933, Moe, 1965, Mugrage and Andresen, 1936, Sjostand, 1949, Smith, 1959, Smith, 1966, Wintrobe, 1961, Wolman, 1957).

The decline in red cell count is gradual in onset, but after the second week becomes marked, reaching a low point at from 6 weeks to 5 months. Most investigators report minima approximately 1.5 million cells per cubic millimeter below birth means at about 2 months, with a slow increase thereafter, totaling about 0.7 million/cu mm by puberty. A brief secondary rise in reticulocytes is often observed as red cell proliferation is reactivated. During adolescence there is very little change in erythrocyte count among females—the average RBC from 10 years through middle age ranging from 4 to 5.5 million/cu mm. Males, however, have a decided increment, amounting to about 0.3 million/cu mm from 10 to 14 and an equal increase between 14 and 17 years, for which rising testosterone secretion is probably the stimulus. The administration of testosterone to children with certain forms of anemia, to eunuchs, and to female or castrated male experimental animals produces a greater volume of red cells (McCullagh and Jones, 1942, Shahidi and Diamond, 1959, Van Dyke, Coutopoulos, Williams, Simpson, Lawrence, and Evans, 1954).

Across both species and age, erythrocyte count and size are negatively correlated (Wintrobe, 1961). Although average cell size decreases during gestation, it is still very large at birth (mean corpuscular vol-

me of 106-125 μ and mean corpuscular diameter of 8-9 μ) The decline in size begins immediately, reaching a minimum MCV of 71-77 μ at 6 to 12 months and a minimum MCD of 5-7 μ at from 3 to 12 months Between 12 and 18 months the trend reverses, but cell size remains below the adult means of 85-90 μ for MCV and 7.2-7.9 μ or MCD at least until puberty

Because red cell size and number decline simultaneously, the drops in hemoglobin per unit volume of blood and in volume of packed cells (hematocrit) are even sharper and the subsequent rise slower than for erythrocyte count Hemoglobin levels decrease by about 8-10 grams per milliliter of blood between birth and 3 to 6 months, then increase by 1.5 to 2 gr/ml by 2 to 5 years The levels remain fairly steady throughout the remainder of childhood There is a further increase of about 0.5 gm/ml for females between 14 and 17 years Males have increments of 1 gm/ml between 10 and 14 years, 1.5 gr between 14 and 17, and 0.5 gr from then to adulthood The hematocrit curve, although somewhat more variable from study to study, takes a similar pattern, decreasing from a range of 52-66% in the first few days to a low of 34-37% at 6 weeks to 12 months Very gradual increases beginning in the second or third year bring the means to 38-42% by 5 to 10 years Averages for females increase by only about 1% between 10 and 14, 1% from 14 to 17, and 1% from then to adulthood The increments for males during these periods are 3%, 4%, and 2%, respectively Since there are no sex differences in cell size nor in the average hemoglobin content per cell, the greater hematocrit and total hemoglobin content of the blood in males is attributable to their higher erythrocyte count

For the most part, the decline in mean corpuscular hemoglobin parallels that in mean corpuscular volume, so mean corpuscular hemoglobin concentration stays quite steady However, during the first few weeks to 2 months when newer, smaller cells are beginning to appear the decrease in MCV is not matched by that in MCH, and the MCHC rises slightly A slight decline thereafter to a minimum at about 2 years is also reported in several of the studies cited above

Considerable controversy has surrounded

the question of whether the osmotic and mechanical fragility of infants' erythrocytes was greater than in older persons There is little question that when tested *in vitro* or by injection into an adult, the life span of neonatal red cells is shorter than that of adult cells The decreased rate of red cell proliferation rather than a difference in the quality of cells is now, however, believed to account for the faster rate of breakdown of the neonatal erythrocytes (Smith, 1959, Smith, 1966) With more old cells and fewer new ones in the blood of the young infant, a reduction in the mean life span would be predictable

White Cells

The five major types of white cell (leukocyte) normally found in adult blood are neutrophils, eosinophils, basophils, lymphocytes, and monocytes In contrast to red cells, all leukocytes are large and nucleated, but the various types and subgroups within them can be differentiated on the basis of the structure of the nucleus, whether or not the cytoplasm contains granules, and staining properties Each category also has a characteristic size range Collectively, neutrophils, eosinophils, and basophils are called granulocytes, in recognition of their granular cytoplasm, or polymorphonuclear leukocytes, because their nuclei are lobulated

Granulocytes are considered to differentiate in the bone marrow from myeloblasts into promyelocytes, myelocytes, and metamyelocytes During the myelocyte stage the granules in different cells acquire distinctive staining affinities, so from that point the precursors of neutrophils, eosinophils, and basophils can be discriminated Before being released into the circulation, lymphocytes pass through two stages, the lymphoblast and the prolymphocyte The precursor of the monocyte is the monoblast

Neither the functions of white cells nor the factors governing their formation are well understood However, both the total number of circulating leukocytes and the proportions of the various types are known to fluctuate not only from day to day but within a single day in the presence of microorganisms and allergens and in response to physical exertion and pain or other mental stress Except for lymphocytes, white cells apparently are

drawn to the sites where they are needed primarily by chemical stimuli, such as the release of nucleic acid from destroyed tissue. When the demand for white cells increases, both the rate of production and the degree of mobilization of cells from storage areas rises. On the other hand, the white cells move quite rapidly from the blood into affected tissue. Further, a condition that stimulates an increase in one class of white cell may reduce the numbers of another. For example, glucocorticoids from the adrenal cortex, the secretion of which increases during stress, lower the lymphocyte count, both by destroying lymphocytes and by inhibiting their production. These hormones also decrease the numbers of eosinophils and basophils in the circulation and increase the neutrophil, platelet, and red cell counts. The concurrent existence of factors promoting and reducing the total number and proportions of white cells underlies the wide and frequent variations observed and makes for some discrepancies in the norms provided by different authorities and in estimates of the life span of leukocytes. Nevertheless, because the proportions of white cells do increase or decrease differentially under various conditions, a differential count, that is, separate counts of each major type, is often of more significance than a combined total count.

Under basal conditions the total white cell count in adults is 4000-7000, although it may rise to 10,000-11,000 with normal activities. Mature neutrophils with a segmented nucleus consisting of 2 to 5 lobes constitute 50-65% of all leukocytes, and nonsegmented forms, known as stab or staff cells, make up another 4-5%. In the advent of invasion of the body by bacteria that cause fever, the number of neutrophils increases markedly and promptly. These cells are very mobile and can pass through capillary walls, a process called diapedesis, to phagocytize bacteria. They also transport pathogenic organisms to lymph nodes, where other phagocytes assist in their destruction, and sometimes carry portions of disintegrated red cells back to the bone marrow.

The granules in both neutrophils and eosinophils seem to be lysosomes that help to digest phagocytized matter, but eosinophils are apparently not as active or sturdy as

neutrophils. Eosinophils phagocytize antigen-antibody complexes, and their proportion, normally about 1-4% of white cells, is increased in persons with allergies and after anaphylactic reactions (extreme sensitivity to foreign matter). However, the action against allergens does not begin as rapidly as does the attack of neutrophils on bacteria. Elevated eosinophil counts also accompany parasitic infections, skin diseases, and blood disorders.

Very little is known about the functions of basophils, which number only 0.1-0.4% of white cells. Although they contain heparin, an acid that prevents clotting, their role in the total system controlling the coagulation of blood or its prevention has not been determined.

All granulocytes are short-lived, circulating for durations estimated at between 2 days and 2 weeks. Like erythrocytes, they are destroyed by the reticuloendothelial system.

Some 20-40% of leukocytes are lymphocytes. They exist in the blood in both small and large forms, the former being more numerous, and they are highly motile cells. Considerable evidence has accumulated to indicate that during gestation and early infancy a substance secreted by the thymus renders the lymphocytes capable of making the antibodies that produce delayed hypersensitivity reactions and rejection of tissue transplants from other organisms (Altmeppen and Smith, 1965; Berman, 1963; Burnet, 1962; Dameshek, 1962, 1963; Fichtelius, 1958a, 1958b; Gitlin, 1964; Gorman and Chandler, 1964; Miller, 1964, 1966). There may be two populations of small lymphocytes, one arising in the thymus and "seeding" other lymphoid organs with immunologically competent cells and a second with some different function. Two subgroups of lymphocytes, not necessarily the same ones, have also been distinguished on the basis of life-span. Some survive for only several days, while others circulate for 100-200 days.

Monocytes constitute 5 to 10% of the circulating leukocytes. They, too, possess amoeboid movement but are less active than neutrophils or lymphocytes. Because monocytes are larger than most of the other white cells, they can phagocytize whole red cells as well as fragments of nuclei and cytoplasm. In

addition, they may have some function in antibody formation. The number of monocytes is increased in the acute phase of rheumatic fever, in active tuberculosis, and in the recovery phases of pneumonia and other acute infections.

Although the primitive blood cells are believed to have the potential to produce leukocytes as well as erythrocytes, very few white cells are found in the blood during the mesoblastic period (Bloom and Bartelmez, 1940; Matsuda, Schroeder, Jones, and Weliky, 1960; Smith, 1966; Thomas and Yoffey, 1962; Wintrobe, 1961). There is some disagreement as to the time of appearance of different classes of white cells and their relative proportions during the first half of gestation. According to some older studies (Doan, 1932; Knoll, 1949, cited in Smith, 1966, and in Wintrobe, 1961; Zanaty, 1934, cited in Wintrobe, 1961), the majority of white cells in the blood during the second month are myeloblasts and about 25% are more mature forms of granulocytes. The granulocyte count rises to fairly large numbers by the fourth month, at which time the first small lymphocytes, like those in adult blood, appear. More recently, however, Playfair, Wolfendale, and Kay (1963) and Thomas and Yoffey (1962) have reported that over half of the white cells found in the circulation in the second month are lymphocytes, and that their numbers increase rapidly from the tenth to the twenty-fifth week and more slowly thereafter. Playfair et al. (1963) detected mature granulocytes in fetuses about 10 weeks of age with a subsequent steady increase, whereas Thomas and Yoffey (1962) state that the small quantity of granulocytes did not begin to be augmented until the twenty-sixth week.

Granulocytes are found in the yolk sac and liver during the hepatic period, and the thymus produces not only lymphocytes but also a few myelocytes. Until the fifth month the spleen is primarily engaged in the proliferation of red cells, but then lymphocyte formation becomes predominant.

At birth the total white cell count and the absolute counts for each type of leukocyte are usually very high, but the relative proportions are more like those of the adult than is true later in infancy (Albritton, 1952; Kato, 1935; Smith, 1959; Smith, 1966; Wash-

burn, 1935; Wintrobe, 1961; Wolman, 1957). An occasional newborn has a total count as low as 3600 or as high as 45,000, but the range in most samples is 7000–35,000, with a mean of about 18,000. Proportions of neutrophils, eosinophils, basophils, lymphocytes, and monocytes average approximately 60, 2–3, 0.5, 30, and 6%, respectively. There is some evidence that the leukocytes found in cord blood show poorer amoeboid movement and phagocytic capability than those of adults (Matoth, 1952).

Almost all investigators have observed a prompt increase in the total count (to a mean of 20,000–22,000), most classes of white cells reaching a lifetime high sometime during the first 24 hours. Neutrophils rise to about 70%, whereas lymphocytes drop to about 20%. A peak for monocytes of 9–17% occurs between 3–4 days and 2–3 weeks. Eosinophils may be relatively low at birth and rise to a maximum of 5–6% between the first and fourth day (Kato, 1935; Mitchell, 1955), while the proportion of basophils seems to change very little. Some myelocytes may be present, and young neutrophils (non-segmented and bilobed forms) may constitute as much as 20–40% of the neutrophils.

Between the second and fourth day a sharp decline in total count begins and continues for a few days to two weeks. Then a small increase ensues for several weeks or months, followed by a slow decline to adult levels at puberty or during early adolescence. Fluctuations in the neutrophil and lymphocyte counts are responsible for this curvilinear trend, for the numbers of other white cells decline gradually. The outstanding developmental trend is a reversal in the relative proportions of these cells. After the immediate postnatal increase, the total numbers of neutrophils decline for a week or two and then rise gradually to the adult value sometime between mid-childhood and puberty. The percentage of neutrophils, however, declines from its early peak of about 70% to a low of 30–32% between the second week and the sixth month, rising to the adult proportion by late childhood or early adolescence. At the same time the lymphocyte count follows the pattern of the total white cell curve, but the proportions are almost the inverse of those for neutrophils. From a minimum of about 20% at the end of the

first day, the percentage of lymphocytes increases to approximately 60% by 2 weeks to 6 months, then decreases gradually to the adult level of about 30% between mid-childhood and puberty

Changes in the availability of oxygen would not be expected to influence the neonatal white cell count, since variations in altitude have little effect on adult counts (Smith, 1959). In addition, white cells are known to require a good oxygen supply for their development (Smith, 1966), so a decline in white cells soon after birth cannot be explained in terms of an improved oxygen supply. Although dehydration might produce the brief postnatal increase in total white cell count, it does not account for the shifts in relative proportions of different types of white cells. The most reasonable hypothesis that has been offered for the latter phenomenon is the transition at birth from a relatively sterile environment to a germ-filled one (Allansmith, 1966, Kato, 1935). An increase in granulocytes is the typical reaction of older persons to infection.

Individual differences in white cell counts are greater than those among adults, at least until puberty. The range is so great during early infancy that an elevated white cell count is of little diagnostic utility. Other aspects of the white cell picture also lack the significance they have in adults (Smith, 1966). Before fat begins to infiltrate the bone marrow, a relatively mild infection may result in a disproportionate increase in white cell count, and in severe infections myelocytes and metamyelocytes may be released into the circulation. Immature lymphocytes appear in the circulation of infants and children more often than they do in adults, particularly in the presence of chronic upper respiratory infections and enlarged tonsils, and the blood of completely healthy young infants may contain some abnormal lymphocytes similar to those found in older persons with mononucleosis. Children with allergies but no other demonstrable illness may show eosinophil ratios as high as 25% for many years.

Platelets and Coagulation Normal platelets are small, nonnucleated bodies of complex composition and, contrary to earlier opinion, high metabolic activity. They are formed from pseudopodia (protrusions) that

break off from the cytoplasm of megakaryocytes. Originally, megakaryocytes are derived from the primitive blood cells of the embryo, as are erythrocytes and granulocytes. As blood formation shifts from one hemopoietic center to another, megakaryocytes appear successively in the yolk sac, liver, spleen, and bone marrow (Smith, 1966, Wintrobe, 1961). Once the hepatic period is well established the number of megakaryocytes increases. The production of platelets also begins very early, but it is slow until the myeloid period (Windle, 1940). In adults megakaryocytes are probably produced only in the bone marrow, although many are present in the lungs and some in the spleen. The megakaryocytes in these other organs are now assumed to have been carried there after developing in the bone marrow, but they retain the ability to form platelets.

To prevent blood loss from a damaged vessel two processes, hemostasis and thrombosis, occur, and platelets participate in each in several ways. Hemostasis (arrest or escape of blood) takes place through contraction of the vessel walls and adhesion of their surfaces. Platelets carry serotonin, a powerful vasoconstrictor, and release it at the site of injury. In addition, platelets possess properties of adhesiveness and aggregation. The formation of clumps of platelets along the injured vessel wall supplements contraction in arteries and arterioles and is even more important in helping to seal off veins, for they are not so well supplied with contractile muscle.

Thrombosis or clot formation can be regarded in a somewhat arbitrary fashion as consisting of three phases: (1) formation of plasma thromboplastin (intrinsic prothrombinase) and tissue thromboplastin (extrinsic prothrombinase), (2) conversion of prothrombin to thrombin, a step which requires both thromboplastin and calcium, and (3) combination of thrombin and fibrinogen to produce a fibrin clot. Plasma thromboplastin is elaborated more rapidly than is extrinsic prothrombinase. Once the latter has begun to form, however, the two mechanisms function simultaneously. Plasma contains all the elements needed to carry out the complete coagulation sequence, but tissue prothrombin cannot be converted to thrombin

until it has been activated by certain other factors in the blood. At least twelve different "factors" or "principles," four of which are thromboplastin, prothrombin, calcium, and fibrinogen, have been implicated in the clotting process. It may be, however, that clots can be formed even if one is deficient. Platelets either contain or have absorbed on their surfaces (this alternative currently seems the more likely) a large portion of the factors required for coagulation. Some of the specific activities that have been attributed to platelets are participation in the elaboration of thromboplastin, acceleration of the conversion of prothrombin to thrombin and of fibrinogen to fibrin, and neutralization of the anticoagulant activity of heparin.

At birth the shape and size of the platelets are more variable than in older persons (Smith, 1966, Tocantins, 1938). Probably because of methodological difficulties—no method for counting platelets is completely satisfactory or entirely consistent from one user to another—platelet counts equal to, higher than, and lower than those of adults have been reported in newborns (Albritton, 1952, Guest, Brown, and Lahey, 1957, Smith, 1966). The weight of the evidence suggests average counts at the lower end of the adult range increasing gradually to adult means by 3 to 6 months (Albin, Kushner, Murphy, and Zippin, 1961, Grossman, Heyn, and Rozenfeld, 1952, Larnieu, Souhei, and Minkowski, 1952, Merritt and Davidson, 1933).

For some time it has been known that coagulation is delayed in newborn infants and becomes even slower on the second to fourth day. Neither a quantitative nor qualitative deficiency of the platelets *per se* seems to be responsible, however (Smith, 1959). Immaturity of the liver and a "physiologic" deficiency of vitamin K may well be major variables. Drawing on the data of McElfresh (1961) and of Aballi and deLamarens (1962), Smith (1966) has organized a developmental table for nine coagulation factors. Omitted are calcium, of which the normal newborn has adequate blood levels, thromboplastin (a product of the clotting sequence that participates in later phases), and the fibrin-stabilizing factor, which prevents clots from dissolving in certain solvents. The cord blood levels of seven of the nine

factors listed are lower than adult norms. Of these, six are produced in the liver, including all four of the vitamin K-dependent factors.

During the first few days after birth several factors, prothrombin in particular, are reduced below birth values. At 14 days four of the six liver-produced factors have attained low normal levels, one is 23–79% of the adult norm. However, prothrombin may not reach adult levels until the end of the first year (Plum, 1949), and the plasma thromboplastin component (Christmas factor) may remain somewhat low, as revealed in delayed thromboplastin formation, until 6 months (McElfresh, Sharpsteen, and Akabane, 1956). Plasma thromboplastin antecedent (Factor XI) rises almost to adult levels by 2 months (Hilgartner and Smith, 1965). Fibrinogen, one of the liver-made factors not dependent upon vitamin K, develops less rapidly than some other factors in young fetuses (Heikinheimo, 1964), but is only slightly low at birth and is normal by 3 days. The seventh factor deficient at birth, one of those involved in thromboplastin formation, rises to adult levels by 14 days.

Insufficient reserves, liver immaturity, and a bacteria-free intestinal tract all contribute to vitamin K deficiency in the newborn infant. With the ingestion of food, not only is vitamin K absorbed, but intestinal flora that synthesize this vitamin also develop. Administration of vitamin K does more to improve coagulation in the full-term infant than in the premature (Aballi, Banus, deLamarens, and Rozenquarg, 1957), but not all coagulation factors are augmented (Hilgartner and Smith, 1965). Feeding cow's milk also helps to increase prothrombin levels, because breast milk has only about one-fourth as much vitamin K content (Smith, 1959).

Immunology The human body has three systems for defending itself against pathogenic microorganisms (and the toxins that some produce), transplants of foreign tissue, and allergens (other foreign proteins and certain nonprotein substances that cause hypersensitivity reactions). First, barriers such as the skin and the mucosal linings of the respiratory, intestinal, and urogenital tracts and their chemical secretions, in some instances aided by ciliary action (vibration of hairlike processes), help to prevent the entry

of invaders Phagocytes, of which the granular leukocytes are one group, are another line of defense Antibodies constitute the third system

In the discussion of white cells the antibody activity of lymphocytes against allergens and transplants of foreign tissue has already been mentioned Lymphoid tissues also manufacture immunoglobulins, a group of structurally related proteins, each member of which is an antibody complementary to a specific antigen (foreign substance that stimulates production of an antibody) In contrast to barriers and phagocytes, which are species-characteristic, antibody immunity is much more idiosyncratic, being acquired primarily in response to the particular antigens to which a person is exposed Isohemagglutinins (antibodies for blood group agglutinogens found in the species but not in the individual himself) are partial exceptions Some, mainly those for the A and B agglutinogens, appear spontaneously, rather than requiring the stimulus of a specific antigen Additional ones may be formed in response to stimulation, however

Antibodies are carried in the gamma globulin fraction of blood proteins Five classes of gamma globulins differing in physical, chemical, and functional properties have been identified Between 80 and 90% of the immunoglobulins in adult blood are of the class called gamma G in the recommended international nomenclature (*Bulletin of the World Health Organization*, 1964, Vol 30) At least four subclasses of gamma G have been recognized, and they are found in interstitial fluid as well as in blood Most of the antibodies to viruses, bacteria, and toxins belong to this group of immunoglobulins Some specific examples are antibodies to measles, mumps, pertussis, poliomyelitis, diphtheria, tetanus, and influenza

Gamma A class makes up 5-15% of adult circulating immunoglobulins It includes antibodies involved in sensitivity reactions and the release of histamine, but may be like the gamma G class in being heterogeneous in both structure and function The major class of immunoglobulins in external secretions—tears, saliva, secretions of the breast and of the respiratory and intestinal tracts—is gamma A

About 5% of the immunoglobulin popula-

tion of adult serum is of the gamma M class Few gamma M antibodies are found in other body fluids Some of the specific antibodies in the gamma M class are the isohemagglutinins, rheumatoid factors, cold agglutinins, Wasserman antibodies, and antibodies against some of the group of bacteria known as gram negative However, protective, although very low titer (concentration) of antibodies against most antigens have been discovered in this class One antigen may be opposed by several different antibodies, and in some instances in which there are antibodies of both gamma M and gamma G classes for the same antigen the former are several hundred times more potent (Robbins Kenny, and Sutter, 1965)

Two minor groups of immunoglobulins, gamma D and gamma E, have also been identified, but virtually nothing is known about the functions or development of these two classes

The duration of immunity to different types of infections varies with the "memory" of the immunological system for the antigen in question and with the specificity of the pathogen The life span of circulating antibodies is quite short—gamma G, A, and M immunoglobulins have a half-life in serum of about 23, 6, and 5 days, respectively However, antibodies for certain microorganisms and toxins circulate long after recovery from the original infection, perhaps because some antigen remains in the body In other instances an antibody disappears from the blood, but if the antigen is later reintroduced the speed with which that antibody is produced is greater than in the first attack—the lymphoid tissue "remembers" how to make it The measles virus is an example of an antigen that is both highly specific and to which resistance, once acquired, is high for very extensive periods of time On the other hand, there are hosts of bacteria and viruses that cause upper respiratory infections with very similar symptoms Young children frequently have such disorders, but after exposure to a sufficient variety of the antigens usually found in their environments, the incidence of upper respiratory infections decreases

As techniques for the stimulation and detection of antibody formation have improved, three long-held beliefs about the immunologi-

cal status of the human fetus and young infant have been refuted. They are (1) the infant is immunologically incompetent until some months after birth, (2) antigens do not pass the placenta, (3) the neonate has not developed his blood group. Supporting these assertions were a number of observations. The immunoglobulins in the fetal and neonatal circulation seemed to be almost entirely of maternal origin, grafts of foreign tissue were rejected less rapidly by newborns than by older persons, the response of neonates to artificial immunization was very limited, the isoagglutinins in the serum of young infants were passively acquired from the mother *in utero*, and the A and B blood group agglutinogens were weaker at birth than at later ages (see reviews by Evans and Smith, 1963, Miller, 1966, Smith, 1959, Smith, 1966). None of this evidence has been completely contradicted, but additional facts have shown that the inferences drawn from them were not justified.

From about the twentieth fetal week, when lymphoid tissue is established in the spleen and lymph nodes—the thymus appears at 12 weeks (Kay, cited in R. T. Smith, 1966)—gamma G and M immunoglobulins can be detected in the spleen and in a small number of cells in the blood (van Furth, Schuit, and Hijmans, 1965). The latter, particularly those of the gamma G class, could be of maternal origin, because transfer of this type of immunoglobulin to the fetus begins very early in gestation, increases gradually until the eighth month, and then seems to rise quite abruptly (Pfau, 1954). Good evidence for fetal synthesis of gamma G immunoglobulins has been adduced, however (Fudenberg and Fudenberg, 1964, Martenson and Fudenberg, 1965), and it is now thought that very small amounts are produced throughout the latter two-thirds of gestation (Allansmith, 1966, R. T. Smith, 1966).

Contrary to the widely quoted results of Hitzig (1963), those of other investigators demonstrate the presence of gamma M immunoglobulins in the serum of almost all infants at birth, albeit at very low titers—5–14% of adult levels (Allansmith and Buell, 1964, Franklin and Kunkel, 1958, Fulginiti, Sieber, Claman, and Merrill, 1966, West, Hong, and Holland, 1962). Such gamma M

immunoglobulins as are present in the fetus are almost entirely self-produced rather than being passively acquired from the mother (Gitlin, Kumate, Uristi, and Morales, 1964, Kochwa, Rosenfield, Tallal, and Wasserman, 1961).

Only rarely have gamma A immunoglobulins been found to cross the placenta or be produced by the fetus (Allansmith, Maloney, and Wymel, 1966, Fulginiti, Sieber, Claman, and Merrill, 1966). All statements about the absence of any class of immunoglobulins in any subject should, however, be qualified by the adjective detectable, because no assay technique is completely sensitive, and techniques vary in sensitivity. For example, the minimum levels per 100 ml of serum detectable by the tests used by Fulginiti et al (1966) were 20–40 mg for gamma G, 4–14 mg for gamma A, and 6–15 mg for gamma M immunoglobulins.

At full-term delivery gamma G levels equal to, higher than, and lower than those in the maternal serum have been observed. All investigators agree that the titers in the infant's blood begin to decline almost immediately, but the lowest point has been reported at ages from 3 weeks to 6 months (Allansmith, 1966, Allansmith, Maloney, and Wymel, 1966, Barrett and Volwiler, 1957, Bridges, Condie, Zak, and Good, 1959, Hitzig, 1963, Oberman, Gregory, Burke, Ross, and Rice, 1956, Orlanini, Sass-Kortsak, and Ebbs, 1955, Stiehm and Fudenberg, 1965, West, Hong, and Holland, 1962). The decline occurs because maternal gamma G immunoglobulins disappear steadily, and replacement by immunoglobulins synthesized by the infant is not sufficiently rapid. Active production of gamma G immunoglobulins is established in most infants by 3 to 6 weeks (Allansmith, 1966, R. T. Smith, 1966), but several more months may be required before the supply is large enough to reverse the overall decline in blood levels.

In one large cross-sectional sample aged birth to 16 years (Allansmith, 1966), the mean gamma G titer was within the lower levels of the adult range by the end of the first year. Increases continued to 18 months, when there was a reversal to about the 12-month mean which lasted until 3 years. Thereafter the average titer began to climb again and had not reached a plateau at 16

years. Mean levels more than doubled between 24 and 52 weeks in infants observed by Fulginiti et al (1966), and by the latter age were about three-fourths of the adult average. Several studies show adult means to be approximated between 1 and 7 years (Bridges, Condie, Zak, and Good, 1959, R. T. Smith, 1966).

Among adults the level of gamma A immunoglobulins usually considerably exceeds that for the gamma M class, but the reverse is true in infants. Relative levels shift between the third and sixth year. Probably because of insufficiently sensitive tests, some investigators have not detected gamma A immunoglobulins in the sera of infants until after the third month (Hitzig, 1963, West, Hong, and Holland, 1962). However, 23 of 27 infants tested by Fulginiti et al (1966) at 6 weeks had this class of immunoglobulins, as did all 21 of the group assayed at 12 weeks. The mean was about 20% of the adult level at 1 year. In other studies gamma A production was found to be well established by the end of the first month (Allansmith, 1966, Allansmith, Maloney, and Wymer, 1966). Longitudinal observations showed the first appearance of this class to be between the fifth and twenty-eighth day. By the end of the first year, the group average was about one-fourth of the adult's. The curve of subsequent increases seems to parallel that for the gamma G immunoglobulins (Allansmith, 1966, Hitzig, 1963, West, Hong, and Holland, 1962), although Allansmith's (1966) data strongly suggest an adolescent spurt in the gamma A titers of girls.

That the greatest proportion of the post-natal increase in gamma M immunoglobulins occurs during the first year is a generalization supported by all the data available. A rapid rise during the second and third months, with levels above those of adults being reached by 6 to 12 months, characterizes some observations (Hitzig, 1963, R. T. Smith, 1966; West, Hong, and Holland, 1962). From cross-sectional sampling at birth and at 6, 12, 24, and 52 weeks (Fulginiti et al, 1966), a marked increment between birth and 6 weeks and a more gradual rise thereafter to somewhat over 50% of the adult mean by 52 weeks would be inferred. Frequent longitudinal sampling (Allansmith, Maloney, and Wymer, 1966) yielded a group

curve that was positively accelerated during the first week. Following much slower increases in the second week and little change in the next two, a decrease ensued at the end of the first month. Most individual curves, however, were steplike in pattern, plateaus alternating with steep rises. Allansmith's (1966) cross-sectional data also show a drop in gamma M immunoglobulins at about 30 days. The titers then rise to adult levels by 10-12 months and even higher by about 2 years. Another decline seems to take place sometime between 2 and 4 years. West, Hong, and Holland (1962) also report a decrease between the first and fourth year. From 4 to 16 years the means fluctuate irregularly with no real trend.

The immunoglobulin levels of infants are generally far less stable than those of adults (Allansmith, 1966). Even though the adult responds to antigens, synthesis of new antibodies seems to be balanced by the disappearance of old ones. At least in part the fluctuations in infants may result from competition for the antibody activity of an immature system, that is, synthesis of one class of immunoglobulins is curtailed when production of another rises.

In addition to assays of classes of immunoglobulins, there is also a considerable body of data on the specific antibodies to be found in the circulation at birth. Smith (1959) provides a good review of this literature. Given adequate concentrations in the maternal blood, the fetus acquires antibodies to diphtheria and tetanus toxins and to the viruses causing measles, mumps, poliomyelitis, and Coxsackie infection which continue to provide protection for as long as 6 to 12 months after delivery. Passive immunity of shorter duration has been demonstrated to streptococcal and staphylococcal infections, influenza and typhoid "H" bacilli, and to pneumococci. If the mother receives large injections of diphtheria toxoid or pertussis (whooping cough) vaccine during pregnancy, the fetus itself seems to produce antibodies as well as to receive larger quantities from the mother. Apparently neonates are fairly susceptible to pertussis because maternal antibodies usually are low rather than because this antibody cannot pass the placenta.

The relative resistance of the placenta to

the transfer of gamma M immunoglobulins is reflected in the low blood titers of the newborn for antibodies to typhoid "O" bacillus, epidemic diarrhea, and other intestinal infections caused by bacteria of the *E. coli* strain. On the other hand, the fact that this class of immunoglobulins does not easily pass the placenta serves to protect the fetus to a considerable extent from hemolytic disorders, because isoagglutinins for the A and B blood group antigens and the saline ("complete" or "agglutinating") type of Rh antibodies are carried by gamma M immunoglobulins. The "incomplete" or "blocking" Rh antibodies, which are transferred more readily, are of the gamma G class.

Unfortunately, the placenta is not completely impermeable to maternal isohemagglutinins, nor, contrary to assertions in even current reviews, is the human infant incapable of synthesizing "natural" A and B agglutinins until the third to sixth postnatal month. Low levels of anti-A or anti-B or both types of saline-active isohemagglutinins were detected in the cord sera of 148 of 250 newborns examined recently (Thomaidis, Fouskaris, and Matsaniotis, 1967). As should be the case, no isohemagglutinins were found in the cord sera of 50 infants with O blood type. Of those infants who did have A or B agglutinins, the source could not be determined in 130 cases. Ten had isohemagglutinins appropriate to the maternal blood type but not to their own. Such instances of ABO isoimmunization by placental passage of maternal agglutinins have been reported previously (Morville, 1929, Smith, 1928, Tovey, 1945). Heretofore it has been assumed that all cases of hemolytic disorder resulting from fetal-maternal blood group incompatibilities or from failure to match bloods before transfusing neonates arose in this way. Another eight infants, however, had A or B agglutinins that could not, because of fetal-maternal differences in blood type, have been of maternal origin.

The appearance of A and B isoagglutinogens early in the second fetal month with subsequent increases in levels was established some years ago (Levine, Burnham, Katzin, and Vogel, 1941, Smith, 1928). Rh, M, N, C, D, and E agglutinogens have also been identified late in the second prenatal month (Bornstein and Israel, 1942, Chown and

Lewis, 1948). The strength of the A antigen increases markedly during the first five postnatal months and more gradually thereafter, approximating adult levels by 2 to 4 years (Grundbacher, 1964). There are also definite variations in the strength of the A antigens and the A₁ and A₂ subtypes (Grundbacher, 1965). Other antigens have not been as well studied, but it has been asserted that the B antigen in fetal erythrocytes is also not as potent as at later ages (Grundbacher, 1964). Nevertheless, the newborn "has a blood type," and the Grundbacher study suggests that neonates are also able to produce isohemagglutinins.

Although both the fetus and the newborn have been shown to be immunologically competent, the neonate may not react as adequately as older children to antigens in terms of either the quantity of antibodies produced or the speed of proliferation. It has been reported that responses to smallpox vaccination and to immunization for pertussis and diphtheria are not as good during the early postnatal months as later. However, the problem of poor response is largely eliminated if a sufficiently potent smallpox vaccine is used (Espmark and Rabo, 1965). In diphtheria immunization there seems to be an age difference in the effectiveness of different types of antigens (Smith, 1959). Immaturity of the immunological mechanisms is one possible factor limiting the response of young infants to antigens. However, the premature infant may become immunologically competent at about the same rate as the full-term one (Uhl, Dancis, and Neumann, 1960), suggesting that environmental factors, that is, the extent of exposure to antigens, may be more influential (Miller, 1966). Complications are posed by the fact that upon leaving the uterine environment the infant is suddenly exposed to a flood of antigens competing for the antibody activity of an underdeveloped, or at least relatively unpracticed, system. Immunity acquired from the mother prenatally may also interfere with the infant's responsivity. However, breast milk offers no significant protection to the human infant (Smith, 1959) and hence may be inferred not to constitute another possible source of inhibition to antibody synthesis by the infant himself.

Although the fetus is considered to be

shielded from infectious agents, clinical data indicate the presence of fetal disease not only in cases of placental pathology but also when the placenta is apparently normal (Smith, 1959). The filterable viruses in particular seem to pass the intact placenta. Infants have been born with signs of measles, mumps, chickenpox, smallpox, and poliomyelitis or have developed the disease so soon after delivery that it must have been contracted prenatally when there was no sign of placental damage. The mother, however, had had the infection during pregnancy.

CIRCULATION

Course of Circulation

Between the beginning of the fourth week, when the embryonic circulation is established, and the end of the second month, when the state prevailing during the remainder of gestation is reached, many innovations and renovations take place in the cardiovascular system. Several were mentioned in the preceding section and a few more, necessary to the understanding of the fetal circulation, will be described here. There is also a brief neonatal transition period during which the course of the fetal circulation, diagrammed schematically in Fig. 1, is converted to the postnatal condition sketched in Fig. 2. General circulation in the adult will be outlined first to facilitate appreciation of the differences between it and the prenatal version and of the transitions that must be made after birth.

Deoxygenated venous blood returns from the systemic circulation (the greater part of the circulatory system, excluding the pulmonary circulation) through two large veins, the superior vena cava (serving the head and arms) and the inferior vena cava (serving the trunk and legs). It enters both the right atrium and the right ventricle, since the valve between the two chambers is open. Then the atrium contracts, forcing more blood through the open valve into the ventricle, which becomes distended as this extra blood is added to that already in the ventricle from passive filling. Next the ventricle contracts, and blood moves behind the cusps of the valve between atrium and ventricle, closing it, so blood is driven through the

valves opening into the pulmonary artery. The pulmonary artery divides into two branches, one to each lung. After giving up carbon dioxide and taking up oxygen in the capillaries surrounding the alveoli of the lungs, the blood returns through veins that unite to form larger veins and finally reaches the left atrium through one of the two pulmonary veins. The left atrium contracts, forcing blood through the open valve into the left ventricle. Blood then closes this valve in the same manner in which it closes the valve between the right atrium and ventricle, so that when the left ventricle contracts blood is forced through the open valve into the aorta, and on through the systemic circulation. Of course, these processes go on simultaneously, all parts of the heart and circulatory system being in almost constant action.

Figure 1 shows five structures that alter the course of the circulation in the fetus—the foramen ovale, ductus arteriosus, ductus venosus, umbilical vein, and umbilical arteries. As noted in the preceding section, the original pair of umbilical veins coalesces into one. During most of gestation the circulatory system consists of two distinct arcs of afferent and efferent vessels—the intraembryonic or systemic and the extraembryonic, the vitelline arteries and veins running to and from the yolk sac have by this time been abandoned. All sets of channels have in common a receiving and pumping organ, the heart, and a primary distributing vessel, the aorta.

During fetal life most of the blood entering the right atrium comes from the superior vena cava. The major portion of blood coming up the inferior vena cava is detoured through the foramen ovale directly into the left atrium, which is closer to the inferior vena cava than it is in the adult. A projection of the anterior rim of the foramen ovale, the crista dividens, diverts some of the flow, but probably more important is the proximity of cava and atrium and the fact that the pressure on the caval side of the valve is greater than that in the left atrium. Although the location of the foramen ovale in the fetus was correctly pictured by Barclay, Franklin, and Prichard (1944) and by Barcroft (1946) several decades ago and, indeed, four centuries ago by Fabricius (translated by Adelman, 1942), most descriptions

Fig 1 Fetal circulation

and diagrams place this valve in its eventual postnatal position between the right and left atria. The student should not be misled by the frequent repetition of this error. An excellent diagram by Born, Dawes, Mott, and

Widdicombe (1954), reproduced in a number of articles in which the placement of the foramen is misstated, illustrates the true position clearly.

A smaller part of the inferior caval stream,

some of which may be blood eddying back from the foramen ovale, goes on to enter the right atrium along with the blood returned from the upper end of the fetus in the superior vena cava. Not all the blood that flows from the right ventricle into the pulmonary artery actually reaches the lungs and returns to the left atrium. Because the lungs must be nourished while unexpanded and non-functional, a small amount takes this adult course. More blood starts along the route than the unexpanded lungs can accept, however, and a shunt, the ductus arteriosus, permits a substantial amount to bypass the lungs and go directly into the aorta. As the

lungs increase in size, so does the pulmonary circulation, but throughout the fetal period it remains very slight relative to the post-natal flow.

The foramen ovale and the ductus arteriosus provide mechanisms whereby the loads on the different parts of the heart are kept approximately balanced. While the lungs are small, very little flow through the right ventricle would be possible if the bypass offered by the ductus arteriosus did not exist. With an increasing pulmonary circulation, less blood needs to be shunted, more returns to the left atrium from the lung, and the amount of blood passing from the inferior vena cava

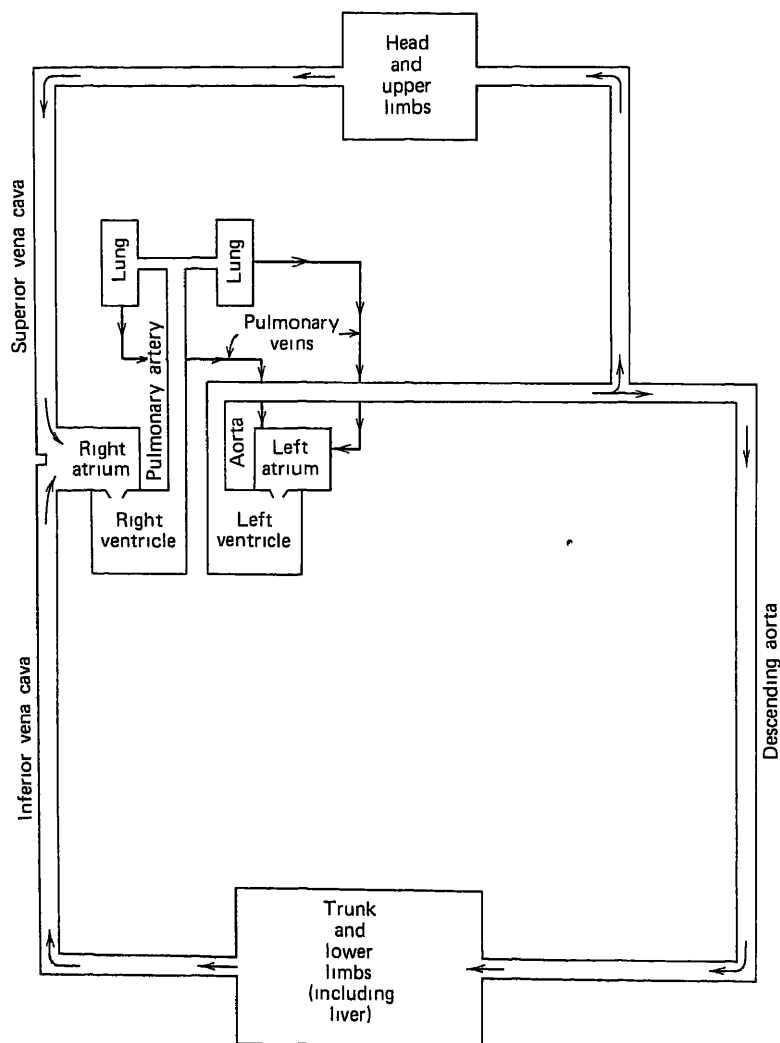

Fig 2 Postnatal circulation

to the left atrium by way of the foramen ovale declines. The approximate equalization of pumping load means that muscle on both sides of the heart is stimulated to develop. If there were no shunt such as that through the ductus arteriosus, the right ventricle would be less well prepared for the work it must perform as soon as breathing expands the lungs and the pulmonary circulation increases dramatically.

Blood coming into the left atrium from the lungs and through the foramen ovale is ejected into the left ventricle and then out into the aorta, as it is in the adult. From the aorta it also follows the adult course into the systemic circulation, some going to the head, neck, and arms via the ascending aorta and returning to the right atrium in the superior vena cava and part going to the trunk and legs in the descending aorta and returning to the left and right atria through the inferior vena cava. In the fetus, however, a large portion of the blood moving down the dorsal aorta passes out the umbilical arteries to the placenta to give up carbon dioxide and wastes and pick up oxygen and nutrients.

When well-oxygenated blood is brought back to the fetus through the umbilical vein it enters the left side of the liver. Here it takes one of two paths to the inferior vena cava. The first is indirect, via the network of sinusoids that began to develop when the liver first interrupted the course of the umbilical veins. The other is a direct shunt to the inferior vena cava, the ductus venosus, which formed slightly later as the volume of blood in the coalesced umbilical vein became larger. Whether or not blood takes this course has been thought to be determined by the opening and closing of a sphincter at the entrance of the ductus venosus (Bailey, Franklin, and Prichard, 1944, Nesbitt, 1966, Reynolds, 1953, Smith, 1959). How constriction would be controlled is not really understood, but innervation by a branch of the vagus nerve and responsiveness to shifts in blood pressure within the umbilical vein have been proposed (Reynolds, 1953). If a large volume of blood were driven in from the placenta, as it is when the uterus contracts, the sphincter could close, diverting the blood into the vascular network of the liver. Temporary storage in the liver would

prevent a sudden overloading of the heart. In addition, a decrease in umbilical vein pressure could stimulate constriction of the sphincter. The primary site of resistance to flow in the placental circuit by which pressure is maintained in the umbilical blood vessels is the liver sinusoids rather than the villous capillaries. Were all the blood to bypass the liver, the blood pressure might not be sufficient to keep the umbilical channels open. Contraction of the ductus venosus, forcing blood through the sinusoids, could promote an increase in pressure. However, the histological evidence for a true sphincter has recently been questioned (Lind, 1966).

Before other aspects of the fetal circulation are considered, let us digress to clarify the fact that in the fetus some veins, in particular the umbilical, contain more highly oxygenated blood than do the arteries. Those who think of arteries as carrying oxygenated blood and veins as bearing deoxygenated blood often find this point confusing. In fact, such a definition is not completely applicable even to the adult circulation, for the portal vein, which collects blood from capillaries in the digestive tract, takes blood to the liver rather than directly toward the heart. From the liver the blood is collected into another set of veins and delivered to the inferior vena cava. An accurate conception of arteries and veins that fits all situations is based on the direction of flow and the morphology of the vessel walls. Arteries carry blood away from the heart and are well-supported by smooth muscle and elastic tissue against the high and changing pressures to which they are subjected. Veins carry blood toward the heart under relatively constant conditions of lower pressure and hence have more non-elastic connective tissue in their walls and relatively little muscle or elastic fibers. This definition places the role of the umbilical vein in the proper context.

One of the questions that has intrigued investigators for many years is the extent to which the better oxygenated blood returning to the fetus via the umbilical vein and the liver becomes mixed in the inferior vena cava and the heart with much less oxygenated blood from the systemic circulation. The first definitive, as well as quantitative evidence came from a classic series of studies on the oxygen saturations of blood in the primary

vascular channels of the fetal sheep (Kellogg, 1930, Barclay, Franklin, and Pritchard, 1944, Barcroft, 1946). Later work (Dawes, Mott, and Widdicombe, 1954, Assali and Morris, 1964b, Romney, 1966) refined the gas analysis approach and added information from high-speed cineangiocardigrams of human and other fetuses (Lind and Wigelius, 1954, Reynolds, 1953, Cassels, 1966). The latter technique involves injecting contrast material into the blood so that its movement can be visualized in a cinematic X-ray. Although much of the research has been done under conditions that must be labeled "unphysiologic"—human data have been obtained largely from nonviable fetuses, lower animals have undergone anesthesia, removal from the uterus, and manipulation of the highly sensitive umbilical vessels and maternal and fetal tissue—the results from many sources are remarkably coherent. No quantitative data from direct measurements of oxygen saturation *in utero* are available for human beings, but the picture of blood flow pattern drawn from angiograms differs only in degree, for example, in the amount of flow through a particular region, from that in other species. In the following description figures in parentheses refer to average oxygen saturations in the fetal lamb (Boin, Dawes, Mott, and Widdicombe, 1954).

The blood carried to the liver in the umbilical vein is the most highly oxygenated (80%) of any in the fetal body. Contrary to assertions in the older literature, a considerable amount of it is shunted directly into the inferior vena cava through the ductus venosus. Upon entry it is combined, to an extent still undetermined, with the smaller venous return of poorly oxygenated blood (26–27%) coming from the sinusoids of the liver in the hepatic portal vein and from other veins draining the trunk and legs. Most of this mixed but still relatively highly saturated (67%) inferior caval stream passes through the foramen ovale into the left atrium, as noted. A smaller stream moves on to the right atrium, there to join the blood of low oxygen saturation (31%) returning via the superior vena cava from the head, neck, and arms. It is this mixture of moderately oxygenated blood (52%) that flows from the right ventricle into the pulmonary artery. Some reaches the lungs and returns to the

left atrium, mixes with the more highly oxygenated blood that entered it via the foramen ovale, and passes on to the left ventricle and thence out the aorta to arteries feeding the cephalic end of the fetus. The oxygen saturation (62%) of the blood in the ascending aorta is only slightly lower than that of inferior caval blood entering the left atrium through the foramen ovale (67%).

At the point where the ductus arteriosus merges into the aorta, the remaining, larger portion of blood ejected from the right ventricle is also combined with more highly saturated blood following the course from left atrium to left ventricle to aorta. This mixture flowing down the descending aorta to the trunk, legs, and placenta is a little less oxygenated (58%) than that in the ascending aorta. Recently the concept of a differential in the oxygen pressures of the two systemic circuits has been challenged (Kaiser, 1966). But others maintain that vital organs such as the heart and brain are protected by a good oxygen supply at the expense of less essential tissue (Reynolds, 1953, Cassels, 1966). Given that physiological interactions are far more important in controlling the course of circulation than is the mere anatomical existence of shunts, it is not surprising that discrepancies exist both in data and in their interpretation. Relatively slight changes in heart rate, velocity of blood flow, and relative pressures (such as might occur either normally or in response to experimental manipulations) can modify the distribution of blood and hence its oxygen saturation in a particular channel at any point in time.

Physiological variables are also primary in the transformation of the fetal circulatory system to an adult one. Within moments after birth the normal infant becomes an air-breathing creature, his connection with the placenta is severed, and the transition to the adult type of circulation begins. Yet anatomical closure of most of the special fetal channels is quite slow. How soon these several channels close, anatomically and physiologically, and how closure is brought about are issues that have long concerned both basic scientists and clinicians. Persistent patency of the ductus arteriosus, for example, is one of the most frequently occurring congenital heart disorders and probably plays

a part in the serious and baffling syndrome known as idiopathic respiratory distress. The complex of factors involved in expansion of the lungs requires detailed and separate consideration. Here we shall stress only the role of pulmonary changes in functional control of the transitional circulation.

Whether or not the infant breathes, support by the placenta is short-lived, for its pulsations soon cease even if no one cuts and ties the cord. The umbilical cord of man has no sphincter such as is found in some other species, but its vessels are supplied with smooth muscle—the arteries better than the vein. Constriction of human umbilical vessels has been observed in response to a variety of mechanical, thermal, and chemical stimuli. The portion of the cord within the uterus may be compressed. In addition, sponging or simply handling the cord initiates contractions in both directions from the site of irritation. Following an easy delivery, in which intrauterine compression may be assumed to have been minimal, and with little handling of the cord, blood may flow in the umbilical vessels for several minutes (Stembra, Hodi, and Janda, 1965). On the other hand, blood flow continuing for more than a few minutes is indicative of some abnormality in the transitional circulation (Desmond, Kay, and Megarity, 1959).

Cooling, which takes place when the infant leaves the maternal body and is augmented by evaporation in air, also stimulates constriction of the umbilical vessels. From experiments in which cord blood has been perfused with oxygen or with drugs such as adrenaline and noradrenaline, it has been inferred that both increase in oxygen saturation subsequent to breathing and secretion of catecholamines in response to the stress of birth produce vasoconstriction (Nyberg and Westin, 1957; Panigel, 1962; Smith, 1959).

Whatever the mechanism responsible for cessation of blood flow in the cord may be, elimination of the placental circuit has marked effects on the neonatal circulation. The vast vascular plexus of the placenta receives as much as half of the total cardiac output of the fetus. When this circulatory aid is removed, the venous return through the inferior vena cava to the heart is reduced, as is the pressure in this channel and the

force of blood against the foramen ovale. Breathing usually begins even before cord pulsations cease, and the expansion and ventilation of the large vascular bed of the lungs decrease pulmonary resistance. With an increase in blood flow to the lungs there is also, of course, a greater venous return to the left atrium. The changes in both the placental and pulmonary circulations alter pressure relationships between the right and left atria. Instead of the pressure being higher on the right side, as it was in the fetus, it becomes higher on the left. The hemodynamic balance which made for a right-to-left shunt through the foramen ovale shifts to a left-to-right pressure gradient serving to hold shut the valve of the foramen ovale.

During fetal life the two sides of the heart are at least equally well developed, and the right ventricle may be larger than the left (see below). In the early postnatal period, however, the weight of the right ventricle declines, while the muscle of the left increases markedly. The difference in the thickness and thus the elasticity of the walls of the two ventricles may also help to maintain greater pressure in the left atrium.

Although a high degree of functional closure is achieved within a few minutes after respiration is established, a small amount of right-to-left—that is, fetal—shunting, has been shown to continue for up to eight days in a large proportion of normal human neonates (Lind and Wegelius, 1954; Prec and Cassels, 1955; Condorelli and Ungari, 1960). Because functional closure depends upon pressure relationships, and these in turn depend in part upon pulmonary blood flow, the potential for reversion to the fetal condition exists. Both reversal of flow and failure of functional closure have been observed in asphyxiated newborns (Lind and Wegelius, 1954; James, Burnard, and Rowe, 1961), but such right-to-left shunts do not, in and of themselves, seem to have the detrimental effects in infancy that a patent ductus arteriosus does. However, closure *in utero* does give rise to enlargement of the heart and congestive heart failure (Naeye and Blanc, 1964). Normally, anatomical closure starts within a few days after birth, as the valve begins to adhere to the rim of the foramen ovale and clots form in the hole or holes in the valve, but very often never becomes

complete Scammon and Norris (1918) observed incomplete anatomical closure in 50% of children under the age of 5 years and 25% of persons over 15 or 20 years old. Postmortem data do not necessarily reflect accurately the normal course of closure, but they are our primary source of information.

Removal of the placental circulation obviously terminates the flow of blood through the ductus venosus from the umbilical vein. Nevertheless, if this channel remained open, liver function might be impaired because blood coming to the liver in the portal vein was diverted directly into the inferior vena cava. Because the ductus venosus is so inaccessible anatomically, relatively little is known about its closure or the consequences of its patency. Autopsy data (Scammon and Norris, 1918) indicate that anatomical closure takes place much earlier and more regularly than for the ductus arteriosus and foramen ovale—complete closure is reported in 40% of cases by 1 month, about 75% by 6 weeks, and approximately 100% by 2 to 3 months. Studies in which dyes or radio-opaque substances were injected suggest that functional closure is essentially accomplished within 1–3 hours after delivery (Jegier, Blankenship, and Lind, 1963) but may not be complete for 1 or 2 days (Peltonen and Huovonen, 1965). Since the existence of a true sphincter at the entrance of the ductus venosus has been questioned (see earlier discussion), the mechanism of functional closure is a matter of conjecture.

Much more is known about the time and manner of closing of the ductus arteriosus. This is a very large vessel—almost equal in size to the aortic arch of the full-term fetus, and the results of its failure to close are serious. For these reasons, the ductus arteriosus has attracted attention at least since the time of Galen and has been the subject of a considerable proportion of the large body of research on the transitional circulation that has accumulated during the last decade. Most of the earlier studies were of anatomic closure (Gérard, 1900, Schaeffer, 1914, Noback and Rehman, 1941, Jager and Wollenman, 1942), but it was understood by the end of the last century that while this process ordinarily required some months, physiologic closure took place quite rapidly (Gérard, 1900).

The mechanism for functional closure is contraction of the smooth muscle in the wall of the ductus, and constriction is also the chief means by which the middle portion of the ductus closes anatomically, although thrombosis plays a part. At each end, occlusion takes place through thickening of the tissue. Eventually the ductus becomes a fibrous ligament. According to Scammon and Norris (1918), the incidence of complete anatomic closure is low during the first month, rises to about 50% by 2 months, and is about 90% by the end of the first year. Christie (1930) reported only 12% patency at 2 months and 1% at 1 year.

Work utilizing cineangiographic, indicator dilution, and oxygen analysis techniques (including improved polarography) and electromagnetic measures of blood flow has made it clear that although this vessel contacts very soon after breathing begins, blood may flow through it in either or both directions for as many as 8 days (Eldridge and Hultgren, 1955, Adams and Lind, 1957, Rowe and James, 1957, Bunard, 1958, 1959, Condorelli and Ungari, 1960, Salng, 1960, Moss, Emmanouilides, and Duffie, 1963, Assali and Morris, 1964a, Jegier, Blankenship, Lind and Kitchin, 1964, Gessner, Kiovetz, Benson, Prystowsky, Stenger and Eitzman, 1965).

The direction and volume of blood shunted is influenced by so many variables that the course and timing of functional closure cannot be specified precisely. In general, the normal pattern is quite prompt but incomplete constriction, with some flow continuing in the fetal direction (right-to-left) for an hour or so, followed by bidirectional shunting for about another 6 hours, then left-to-right shunting for a half day or more, and finally complete physiological closure. Pressure changes like those underlying functional closure of the foramen ovale accompany the reversal in direction of flow through the ductus arteriosus. Before delivery, the pressure in the pulmonary arteries is greater than that in the descending aorta. Breathing lowers pulmonary vascular resistance, while removal of the placental vascular bed increases resistance in the systemic circuit. Hence the pressure in the pulmonary artery becomes somewhat lower than that in the aorta. At first flow through the ductus arteriosus may be bidirectional, for crying, coughing, and

the like, can cause temporary pressure shifts that reverse the flow to the fetal direction. However, as constriction of the ductus becomes greater and pulmonary arterial pressure continues to drop, the flow becomes completely left-to-right before ceasing.

Results from both *in vivo* and *in vitro* experiments support the hypothesis that the primary stimulus for functional closure is an increase in oxygen tension (Born, Dawes, Mott, and Rennick, 1956, Assali, Morris, Smith, and Manson, 1963, Kovalčik, 1963, Adams, Moss, and Emmanouilides, 1966). There is also indirect evidence from observations on deliveries at high altitudes (Alzamora et al., 1953, Alzamora-Castro, Battilana, Abugattas, and Sialei, 1960, Peñaloza et al., 1964) and on premature (Powell, 1963, Moss, Emmanouilides, Rettoni, Higashino, and Adams, 1965) and full-term neonates with respiratory distress syndrome (Record and McKeown, 1953, Rudolph, Auld, Golinko, and Paul, 1961). These conditions are associated with an above average incidence of low oxygen saturation, patent ductus arteriosus, and bidirectional shunting.

The ductus is also responsive to adrenaline and noradrenaline (Kennedy and Clark, 1941, 1942, Kovalčik, 1963). Apparently a direct response to chemical stimulation underlies the reactions to oxygen and these catecholamines, for the ductus arteriosus is not known to have autonomic innervation (Boyd, 1941). After several hours, the ductus loses its sensitivity to oxygen and fails to dilate if the oxygen saturation of the blood drops.

The effects of patent ductus arteriosus range from an almost complete lack of symptoms to labored breathing, congestive heart failure, and death, depending in large measure upon the extent to which the channel remains open and the presence of complications (Keith, Rowe, and Vlad, 1967). Susceptibility to fatigue is very common, particularly in younger children, and may in some instances help to prevent overexertion and more serious effects. Among the more severely impaired, growth failure, respiratory infections, and heart murmurs are the most frequent symptoms, and the incidence of heart enlargement is fairly high. When surgery is delayed beyond the age of three years, growth retardation often continues,

even in relatively mild cases. Slow growth, respiratory difficulties, and enlargement of the heart are not, of course, unique to patent ductus arteriosus. This syndrome is typical of any disorder that results in a poor supply of oxygen to the tissues.

Statistics on the incidence of disease cannot be accepted at face value, because of variations in the adequacy of diagnosis, reporting, and follow-up. Further, in mortality data, death is attributed to one cause, although the occurrence of multiple disorders is common. For example, figures on neonatal mortality show respiratory disease as the leading cause of death, while cardiac disease usually ranks about fifth, but the latter is often a complication of the former. Congenital heart disease is known to account for the largest proportion of cardiac disorders in children, and recent studies indicate a much higher incidence than was formerly believed to exist (Keith, Rowe, and Vlad, 1967). Current figures, which may still be too low, show over eight cases of congenital heart disease per thousand births. If stillbirths are excluded, the number drops to six or seven per thousand. However, many of these children succumb during the first year, particularly during the first month.

Given the intricacy of the circulatory system which is developed during gestation, the complexity of the circulatory adjustments to be made at birth, and the hazards imposed by delivery, it is perhaps surprising that most neonates make the transition from fetal to adult circulatory patterns so well. In a large majority, the system functions essentially as an adult one within about three hours after birth, despite the potential for some reversals during the first week or so and anatomical differences of longer duration.

Heart and Blood Vessels

Because modifications in work load are quite promptly reflected in the musculature of the region of the heart affected, the marked developmental changes which occur in the size and form of the heart are of particular interest. In all species that have been examined the walls of the ventricles are about equal in weight until fairly late in gestation, but soon after birth the left ventricle begins to grow more rapidly than

the right and remains larger thereafter. Data on relative size during the interval between these two periods are much less consistent, particularly for the human being. Whether the discrepancies arise from true species differences, variations in method, or from abnormalities associated with the cause of death in man has not been determined.

Equal weights (Keen, 1955) and greater weight of the left ventricle (Brock, 1954) at term have been reported for human infants. However, more studies, especially recent ones, indicate a larger weight gain for the right ventricle from the sixth or seventh fetal month, with as much as a 33% difference in the full-term newborn (Patten, 1933, Emery and MacDonald, 1960, Hort, 1955, 1966). In addition, other kinds of data suggest greater development of the right ventricle in the perinatal period. The total size of the transverse sections of blood vessels leading to and from the right heart exceeds that for the left in the neonate (Patten, 1930/31), and Hort (1966) cites evidence for a greater capacity of the neonatal right ventricle when filled. Also, the most obvious feature of the late prenatal and early neonatal electrocardiogram is right ventricular preponderance (see discussion of Electrocardiogram).

According to some investigators (Brock, 1954, Emery and Mithal, 1961), there is no absolute loss in the weight of the right ventricle, only a slower rate of gain than is characteristic of the left ventricle. But the preponderance of evidence (Keen, 1955, Hort, 1955, 1966, Recavarren and Arias-Stella, 1964) supports Muller's (1883) early finding of real atrophy. Both Keen (1955) and Hort (1955) find a very considerable decrement in weight during the first month, followed by a smaller loss in the second month to a minimum of about 20% of birth weight. Shortly, a slow gain ensues, so that the right ventricle regains its birth weight sometime between 6 and 12 months.

Accepting the pattern of developmental changes in the human ventricles presented by recent studies, Hort (1966) marshalls rather convincing physiological hypotheses to explain the changes observed. He assumes that "the growth or atrophy of the heart muscle is regulated through the systolic force of tension that the muscle fibers develop by

their contraction" (1966, p. 210), and suggests factors that could modulate the force required of the two ventricles late in gestation and after delivery.

The amount of blood reaching the lungs from the right ventricle equals the amount delivered to the left atrium, and hence to the left ventricle, at all times. However, during the fetal period the volume of blood entering the ductus arteriosus from the right ventricle may not always be the same as that passing through the foramen ovale into the left heart. Hort (1966) argues for such a difference during the latter part of gestation. Because the growth rate of the foramen ovale decreases relative to that of the fetus as a whole, the amount of blood that can be shunted through the foramen ovale may not keep pace with the volume coming to the right heart in the superior and inferior vena cavae. More blood would then flow into the right ventricle. If the amount shunted through the ductus arteriosus now exceeds that reaching the left heart through the foramen ovale, the stroke volume of the right ventricle will be increased relative to the left.

The reversal in growth rates of the two ventricles after birth cannot be accounted for by some analogous change in stroke volume. Although the volume of blood returning from the placenta is eliminated, a greater amount reaches the right ventricle from the systemic circulation once the foramen ovale closes, and with constriction of the ductus arteriosus, the stroke volumes of the two ventricles become very similar. The lesser work load of the left ventricle probably stems instead from the lowering of resistance in the lungs and the consequent drop in pulmonary arterial pressure. The level of this pressure determines the tension that the right ventricle must develop to force blood into the pulmonary artery.

For a few days after birth the pressure in the pulmonary artery can vary widely, as mentioned earlier, but on the average it is about equal to the aortic pressure. Then it falls fairly dramatically and continuously until three months, when the mean ratio of aortic to pulmonary pressure approximates that of the adult. Hort (1966) aligned his age curves for the weight of the right ventricle with pressure curves (Rowe and James, 1957) and found them to parallel one another.

other closely. As will be described later, the decline in pulmonary resistance and pressure is concomitant with a postnatal pattern of dilatation and thinning of the small arteries in the lungs.

In contrast to the postnatal course of the right ventricle, the left ventricle increases in weight at a rate greater than that of the body as a whole. The underlying variable may be the rise in pressure in the general circulation which takes place subsequent to a very brief drop in the first hour after birth. By about three months of age, the relative size and form of the various regions of the heart are comparable to those of the adult.

The total weight of the heart at birth constitutes a larger proportion of body weight than it does at most later ages. If placental weight is taken into consideration, however, the ratio of heart to body weight is like that of the adult. Elimination of the placenta reduces the weight of tissue to be served by about 15 to 20%, so the ratio increases slightly during the first month despite very little increment in total heart weight (Smith, 1959, pp 126-128). During the remainder of the first year body weight triples while heart weight only doubles, presumably because of its initial advantage. Thereafter, the rate of growth of the heart almost parallels that of the body it must supply with blood. Between the end of the first year and adulthood, the ratio of heart to total weight declines by about 0.05% in males and 0.10% in females (Muller, 1883).

Although the embryonic and fetal development of vascular channels has been quite thoroughly researched (Arey, 1965; Patten, 1953), surprisingly few data are available on the postnatal growth of the major blood vessels. In the embryonic period the arteries are relatively large, during the remainder of gestation and during childhood, their diameter becomes progressively smaller in proportion to the size of the heart and the body as a whole (White House Conference, 1933). The decreasing heart artery ratio may be a factor in the developmental increase of blood pressure (see below). Existing data indicate that the absolute growth rate of the arteries postnatally is associated with the weight or volume of the regions to which they carry blood.

Current concern about infant respiratory

disorders is reflected in the considerable amount of research on the pulmonary vascular bed (Avery, 1964; Wagenvoort and Wagenvoort, 1966). The walls of the newborn's pulmonary arteries and arterioles, like those of the aorta, are very thick, and the pulmonary trunk and main arteries also have a great many elastic membranes. In the adult the walls of the pulmonary trunk are much thinner than those of the aorta and have little elastic membrane. Differences between the adult and the fetus and newborn in the thickness of the arterial walls are greater yet in the intrapulmonary arteries, particularly the muscular arteries and arterioles.

Soon after respiration is established, the media of the pulmonary vascular channels begins to thin rapidly and continues to do so until about the third week. The decrease is more gradual thereafter, and by 12 to 18 months, the relative thickness of the walls is comparable to that of the adult (Wagenvoort and Wagenvoort, 1966). Dilatation of the vessels rather than atrophy of their tissue is probably responsible for the widening of the lumina of the pulmonary vascular channels.

That developmental variations in the thickness of the smaller blood vessels bear importantly upon modifications in the vascular resistance of the lungs is suggested by other data (Wagenvoort and Wagenvoort, 1966). During gestation, when pulmonary resistance is high, the small arteries and arterioles have relatively thicker walls than do the larger muscular arteries. They apparently dilate more extensively after birth, however, for their walls are thinner in proportion to the diameter of the vessels than are those of the larger arteries until the end of the fourth or fifth week. At this time a slight but permanent reversal to a difference in the fetal direction takes place. Expansion of the small arteries and arterioles should contribute greatly to the reduction in vascular resistance and the resultant rise in blood flow observed in the lungs during the neonatal period.

There is a fairly sizable literature on the structural and functional development of the smallest blood vessels, the capillaries, in various tissues of the human body. From post-mortem analyses on the liver, cerebral cortex, and cerebellum it is known that with advancing gestational age the distance between

capillaries decreases, while the length of the capillary network and the number of capillaries per unit tissue increases rapidly (Mali and Raiha, 1935, Levine and Gordon, 1942, Niemineva, 1950, Niemineva and Tervilla, 1953, Diemer and Henn, 1964). Between full-term birth and adulthood, capillary density per unit tissue triples (Diemer and Henn, 1964), but the timing of the postnatal growth has not been traced. A large increment in the number of cerebral arterioles during the first six postnatal weeks with little systematic growth throughout the remainder of the first year has been reported (Rhodes and Hyde, 1965). However, the authors of that study believe that their failure to demonstrate an increase after six weeks may have a methodological basis.

As was pointed out very early in this chapter, the degree of vascularization of any organ is influenced by its metabolic activity. Diemer and Henn (1964) discuss their finding of a relatively low capillary density in the cortex of the newborn infant in these terms. Unfortunately, definitive development data on the oxygen consumption of the human brain are lacking, the only other evidence for a low cerebral metabolic rate in the neonate is also indirect (Kety, 1955, Keipel-Fronius, Vaiga, and Mestyán, 1961). In lower animals (e.g., the rat) parallels exist between capillary density and oxygen consumption not only for adult and newborn, but also for different regions of the brain at a given age (Himwich, 1951, Flexner, 1955). With respect to the latter fact, it is of interest that the ratio of capillaries in white matter to the total number in the cortex is higher in the newborn (1.2) than in the adult (1.3) (Diemer and Henn, 1964). This observation suggests that the metabolic activity of subcortical tissue is relatively higher in proportion to that of the cortex in the newborn. Myelinated fibers make up the white matter, and little myelination occurs in the cortex prenatally. Regional differences in capillarization within the brain have also been detected in human fetuses beginning quite early in gestation (Craigie, 1945). Analogously, early in the fetal period the oxygen consumption of the thalamus, caudate nucleus, and frontal cortex are low, whereas that of the medulla is relatively high (Himwich, Benardson, and Tucker, 1960). By term

the metabolic activity of the other structures exceeds that of the medulla.

Investigations of capillary fragility have been prompted in part by concern about the susceptibility of the human infant to hemorrhage during labor. Most studies have used the technique of applying suction to induce pressure changes that produce petechiae (small purplish red spots caused by interadermal or submucous hemorrhage). Measured in this way, capillary permeability decreases during gestation and for at least the first postnatal week (see review in Smith, 1959, pp. 137-139). No attempt has been made to verify an early report indicating some decline in capillary resistance after the first few weeks (Abt, Farmer, and Epstein, 1936).

With a quite different approach evidence has also been obtained for a decrease in capillary permeability with age (Celandier, 1966, Celandier and Marild, 1962). The investigators regard their method as simply a means of assessing the extent of the capillary surface area to which blood is flowing. However, they offer no rationale for dismissing the likelihood that differences in permeability are responsible for their findings (Young, 1966). The calf and foot are placed in a water-filled venous occlusion plethysmograph (apparatus for recording volume changes) originally devised to study other aspects of the peripheral circulation in infants (Celandier and Thunell, 1960, 1961, Celandier and Marild, 1962). From the rate of outward filtration at different degrees of occlusion, a capillary filtration coefficient is calculated. This index represents the amount of fluid leaving the blood per unit time and tissue at various levels of capillary blood pressure. Although the capillary filtration coefficient varies with temperature and the volume of blood flow, it is on the average about twice as high in the full-term infant and five times as high in the premature infant as in the adult.

The response of the capillaries of the premature and full-term infant to other physiological stimuli also differs (Ararjavu, 1953, Eckstein, 1936). Neither dilatation after warming nor contraction in response to an injection of adrenalin is as adequate in the premature as in the full-term infant. Upon exposure to cold, however, the capillaries of

the premature contract as promptly as those of the mature newborn

Blood Volume

Plasma volume and red cell volume together make up blood volume. Normally plasma volume is almost constant and alterations in blood volume are caused by changes in red cell volume, which shifts considerably in a variety of circumstances (see discussion of Hematology). The total volume of blood in the body influences, and is influenced by, both fluid balance and cardiovascular function. In addition to the mechanisms controlling water intake and excretion, interchange of water among the fluid compartments (intracellular fluid, interstitial fluid, and plasma) helps to preserve the stability of each.

Intracellular fluid is protected from change at the expense of both other compartments, whereas water passes in and out of the interstitial compartment most readily. If interstitial adjustments are insufficient to sustain intracellular fluid at normal levels, plasma water is reduced or augmented. Diarrhea and vomiting, to which the infant is highly susceptible, are particularly likely to lead to dehydration in young children, because the younger the child, the greater is the relative water content of the body and the larger is the proportion in the extracellular compartments. Other conditions that result in a decrease of plasma volume are hypothyroidism, shock, burns, and hemorrhage.

When a large amount of blood is lost rapidly, pressure is reduced throughout the cardiovascular system. A decrease in venous pressure leads to a drop in cardiac output (volume of blood pumped by the heart each minute), further lowering the arterial pressure. The latter is a major factor in maintaining an adequate flow of blood to all tissues. To compensate for the decline in cardiac output, several reactions occur. A reflex triggers an increase in heart rate (cardiac output is a multiplicative function of stroke volume—the volume of blood ejected at each heart beat—and heart rate). Simultaneously, water is transferred from the interstitial compartment to plasma to restore blood volume to normal.

Blood volume and many of the variables to be considered in later sections are related

to body size or some aspect of it. Neither the course of developmental changes nor some other comparisons such as those between the sexes, can be examined meaningfully unless these measures are expressed in terms of units per body size. Selection of an appropriate referent is, however, often difficult. One problem is that the effective variable may not be weight, height or surface area, but rather the amount of a particular sort of tissue, such as lean body mass. Another is that different-sized units do not bear the same relationship to each other throughout development nor for all body builds at any one age. Illustrative of the former fact is Table 1 (adapted from Smith 1959), which shows that the younger the child, the greater is his surface area relative to his weight.

Table 1

Age	Proportion of Adult Weight	Proportion of Adult Surface Area
4 days, premature	0.024	0.090
15 days	0.048	0.150
6 months	0.080	0.210
1 year	0.145	0.340
6 years	0.250	0.525
12 years	0.340	0.630

As can be inferred from the table, if the underlying variable actually is surface area, weight will not provide a sufficient correction, and the measure per unit weight for an infant or child will be large relative to the adult.

According to the data of Moise, Cassels, and Schultz (1947), the correlation between total blood volume and weight is linear in children aged 1 to 17 years, but the correlations with age, height, and surface area are not. At greater heights or ages, for example, there is a larger increase in blood volume than would be predicted from a linear relationship. Russell (1949) found higher correlations of blood or plasma volume with weight than with height or surface area among children 3 months to 13 years of age. Nevertheless, he advocated height as a standard, because weight is less stable, changing considerably even during the course

of one day with variations in hydration, food intake, and excretion. The standards of Brines, Gibson, and Kunkel (1941) are also based on height. Weight is still a widely used referent, however, particularly for infants and adults.

Probably because of differences in technique and the suitability of size referents, a rather wide range of values for blood volume have been reported at all ages. In principle, blood volume and either of its components can be measured, but in fact all methods have inherent sources of error. Among young infants another important factor is the extent of placental transfusion, and none of the normative data available comes from studies in which this factor has been carefully and systematically controlled.

Blood may be transferred from fetus to placenta, but transfer from placenta to fetus has received more attention. How much blood the infant will gain or lose is influenced by the strength and frequency of uterine contractions, pulsation of the cord, the length of time the cord is left attached, gravity (i.e., the position of the infant relative to the placenta), and whether or not the cord is deliberately "stripped" (see reviews in Moss and Monset-Couchard, 1967, Smith, 1959, Smith, 1966, and Watson and Lowrey, 1967). Increases in infant weight have been observed after each uterine contraction, but decreases occur if the cord pulsates strongly or if the fetus is held above the mother. Most of the effect on weight takes place within a few minutes of delivery, with almost no change after 10 to 20 minutes.

From serial measurements of blood volume in normal full-term infants Usher, Shephard, and Lind (1963) estimated that if the cord were not clamped for 5 minutes the total blood volume of an infant of average birth weight would rise about 60%. Their actual observations show a much smaller increase. One-fourth of the transfusion was accomplished within 15 seconds of birth and one-half to three-fourths by 60 seconds. Within 4 hours of birth the blood volume of infants with delayed clamping was reduced from 99 to 89 ml/kg, presumably because fluid had shifted from plasma to the interstitial compartment. Among infants whose cords had been clamped immediately there were no changes in blood volume during the same

time period. At 3 days these infants had an average blood volume of 82 ml/kg and red cell and plasma volumes of 31 ml/kg and 51 ml/kg, respectively. Infants in the "late-clamping" group had a mean blood volume of 93 ml/kg, red cell volume of 49 ml/kg, and plasma volume of 44 ml/kg.

Most sources indicate that total blood volume is high in the premature infant, intermediate in the full-term infant, and lowest in the adult. The volume of red cells is almost equal for premature and full-term infants and higher in both than in the adult. Plasma volume is quite elevated among the premature, but only slightly so in the normal newborn when comparisons are based on body weight. Representative figures are a total blood volume of 108 ml/kg for the premature, 85-90 ml/kg for the full-term infant, and 75-80 ml/kg for the adult. The adult average is probably approximated by about 2 months.

Among adults the male has a blood volume per unit weight about 16% greater than that of the female. The preponderance of evidence suggests that this difference does not appear until puberty, when red cell volume, total blood volume, and perhaps plasma volume increase more rapidly in the male (Brines, Gibson, and Kunkel, 1941, Sjostand, 1953, Tanner, 1962). Because blood volume seems to be higher in adults with relatively large amounts of muscle (Hicks, Hope, Turnbull, and Verel, 1956) and muscle mass increases more rapidly during adolescence in males, the sex difference in blood volume may arise from a difference in the relative proportions of tissue with high metabolic activity (Tanner, 1962).

Cardiac Output

The cardiac output of the human being is usually measured by some variant of either an indicator dilution or Fick method. For example, a known amount of dye is injected into the right atrium or a large vein, and a curve of the indicator concentration in successive samples of arterial blood is plotted against time. Dividing the amount of indicator injected by its average arterial concentration, with appropriate adjustments for the interval of time involved, yields an estimate of the flow of blood from the heart per minute.

According to the Fick principle, the amount of a substance taken up by an organ in a given amount of time is equal to the arteriovenous difference in the level of the substance multiplied by the blood flow. One way in which this principle can be applied to determine cardiac output is to divide the oxygen consumption of the lungs per unit time by the difference in oxygen content of venous and arterial blood across the lungs. In the direct Fick method oxygen saturation is actually measured, indirect methods utilizing estimates derived in other ways are not very reliable.

As ordinarily used, these procedures measure the output of only the left ventricle. By proper selection of sampling site, right ventricular output can also be measured, but the outputs of the two ventricles may be considered equal after the neonatal period. The existence of shunts so alters the pattern of oxygen or indicator concentrations and timing of indicator dilution curves basic to the calculation of cardiac output from either ventricle that estimates derived from the two ventricles may differ, and both may be inaccurate. Fortunately, techniques for detecting shunts can be incorporated in studies of blood flow.

No measures of cardiac output in the human fetus are available. However, several studies of newborn infants have been reported. An excellent example of problems and methods is a recent study (Gessner, Krovetz, Benson, Prystowsky, Stenger, and Eitzman, 1965), in which a dye dilution technique was used. One catheter with two separated side holes was positioned so that the two sideholes straddled the foramen ovale. Dye could then be injected into either one or both atria at the same time.

Only left atrial curves, that is, curves obtained after separate injection into the left atrium, proved to be suitable for estimating ventricular outputs and the amount of left-to-right shunting. Injection into the right atrium was useful for detecting right-to-left shunts, but shunted blood reappeared at the sampling site (the abdominal artery) before the peak concentration of the initial dye curve had been reached, invalidating the determination of cardiac outputs. Following left atrial injection, shunted blood returned dye to the abdominal artery shortly after the

first peak had been observed. Therefore left ventricular output had to be calculated from a formula in which only the first part of the dye curve is utilized instead of from the standard equation. By adjusting left ventricular output for the extent of left-to-right shunting, the right ventricular output was derived.

The generally rapid circulation time of infants (Blankenship, Lind, and Arcilla, 1965, Gessner et al., 1965, Lesser, Meyer, and Henderson, 1952, Slobody, Rook, Leibaig, and Morey, 1950, Yang, Slobody, Mendlowitz, and Tyree, 1955), particularly in combination with inaccuracies inherent in the customary flush technique for dye injection, also create difficulty in securing reliable dye curves. Circulation time is the interval required for blood to travel from one point in the circulation to another. It can be measured with injected dyes, radioactive isotopes, or a variety of substances that give rise to discriminable reactions, such as flushing or a bitter taste. Among adults the average arm-to-lips time is 14 to 15 seconds, for children aged 2 to 12 years and infants under 2 the means are about 11 and 7 seconds, respectively (Averbuck and Friedman, 1935, Brandfonbrener, Landowne, and Shock, 1955, Hubbard, Preston, and Ross, 1942, Oberst and LaRoche, 1954, Sutliff and Holt, 1925, Witzberger and Cohen, 1943). With the flush technique the instant at which dye begins to enter the circulation cannot be determined, and, unless timing is carefully controlled, the dye may be injected in two doses. A special syringe and injection technique designed to provide instantaneous dye ejection and recording were used in the study of Gessner et al. (1965) summarized above.

Circulation time is directly related to cardiac output, and both of these measures are positively correlated with metabolic rate. When oxygen consumption rises, as it does, for example, during exercise, excitement, eating, or hyperthyroidism, the cardiac output of normal subjects increases to keep the tissues adequately supplied with oxygen. Because cardiac output is associated with metabolism and the latter, in turn, with body size, cardiac output is often reported in terms of the cardiac index, the blood flow in liters per minute per square meter of surface area. The validity of this index is still

being debated, and height has been claimed to be as good a referent (Krovetz, McLoughlin, Mitchell, and Schiebeler, 1967). To date, however, the data available in a form to permit developmental comparisons are based either on surface area or weight.

Under basal conditions the cardiac output of adults averages 70–80 ml/kg/min, or a cardiac index of 3.0–3.2 L/min/sq m of surface area (Dittmer and Giebe, 1959, Hamilton, 1962). Prie and Cassels (1955), the first investigators to measure the cardiac output of the neonate, obtained a mean cardiac index of 2.5 for infants aged 2 to 28 hours. On a weight basis, this would be more than twice the adult output. Dye was injected into the umbilical vein (hence the dye curves are right atrial ones), an ear oximeter was used for sampling, and outputs were calculated from the standard Stewart-Hamilton equation. The oximeter is an inexact instrument for measuring dye concentrations, the problems associated with right atrial curves and timing of injection have been described. Although Adams and Lind (1957) arrived at an almost identical mean and range with the Fick method, they used assumed oxygen consumptions for all but three infants, and the oxygen content of their blood samples may have been affected by shunting. The means in these two studies are close to those estimated by Gessner et al (1965) for right ventricular output, 2.6, but the higher individual values observed are in the range of their mean left ventricular cardiac index, 4.0.

The highest cardiac outputs reported for any age group—348 ml/kg/min for the left ventricle and 348 for the right—are those from Burnard's (1966) work with infants 2 to 28 hours old. He measured right ventricular output by the Fick method and left ventricular output with a thermal dilution technique and injection directly into the left atrium. His simultaneous measures of oxygen consumption are about 50% greater than basal levels for age (see section on Basal Metabolism), indicating that the subjects were not in a basal condition. On the other hand, Gessner et al (1965) made repeated measurements on the same infants during the first 2 hours of life and excluded from analysis any made while the baby was active. Average left ventricular output was about 250 ml/

kg/min. The derived estimate for right output was considerably lower. Their data are also consistent with mean pulmonary blood flows found in other recent studies of neonates (Chu, Clements, Cotton, Klaus, Sweet, Thomas, and Tooley, 1965, Klaus, Braun, and Tooley, 1961) and with data on the neonatal sheep (Cross, Dawes, and Mott, 1959) and rabbit (Dawes and Mestyan, 1963). However, their measures might be invalid if any significant degree of left-to-right shunting through the foramen ovale occurred. Their methods can be assumed to check only on shunting via the ductus arteriosus.

In none of the studies done to date has the effect of placental transfusion been controlled. However, nine of the newborns tested by Gessner et al were delivered by elective caesarean section and had their cords clamped more promptly than the five infants who were delivered vaginally. At about one hour after birth the left and right ventricular outputs were 3.5 and 2.3 L/min/sq m, respectively, for the former group and 5.0 and 3.1 for the latter. The absolute volume of left-to-right shunting was also greater in the babies delivered in the normal way.

Granting the reservations applicable to all the data available and taking account of the particular limitations of some, two inferences may be hazarded. The relatively large surface area of the neonate imposes a functional demand on his heart that is, in terms of his weight, several times that of the adult. Further, some factor, perhaps a higher metabolic rate, makes for a cardiac output larger than the adult's even per unit of surface area.

These conclusions are supported by the results of investigations on older infants and children. Unfortunately, in these studies a single cardiac index is reported for a wide range of ages. With only one exception (Jegier, Sekelj, Davenport, and McGregor, 1961), however, they agree in showing the cardiac index to be above the adult average. Means reported include 4.1 L/min/sq m in children aged 6 to 16 years (Spioul and Simpson, 1964), 4.3 in two groups, one with a mean age of 12 (Brotmacher and Fleming, 1957) and another with an average age of 8.7 years, but a range from less than 1 week to 19.9 years (Krovetz, McLoughlin, Mitchell, and Schiebeler, 1967), and 4.6 in a sam-

ple aged 5 months to 14 years (Agustsson, Bicoiff, and Arcilla, 1963)

Blood Pressure

The pressure exerted by blood against the walls of the vessels that contain it can be measured with varying degrees of difficulty and accuracy in all vascular channels and in the chambers of the heart. When unqualified, the term blood pressure is usually intended to mean the pressure in the aorta and large arteries, particularly the brachial artery in the upper left arm. Systolic pressure is the highest pressure reached in the large arteries during ventricular systole, and diastolic pressure is the minimum to which the pressure falls at the point in ventricular diastole immediately before the beginning of the next systole. If these two pressures are reported jointly, the systolic is, by convention, placed above the diagonal and the diastolic below it, for example, 120/60.

To assess intraarterial pressure directly, a needle which is attached to some measuring and recording device is inserted. Although direct measurements are the most accurate, they have disadvantages, especially when they are to be repeated over a period of time. The apparatus is expensive, and aseptic conditions must be maintained. Indirect methods require a cuff that can be inflated and gradually deflated and a manometer.

The oldest and still the most widely used techniques in routine clinical practice are palpation and auscultation. In palpation a finger is placed on the artery at the wrist or ankle (a leg is often the site of measurement in infants and young children) or just below the cuff. The pressure in the cuff is increased above the expected pressure or until the pulse disappears, and then is lowered in steps until the pulse is felt again. This approach gives an approximation of systolic pressure—about 2-5 mm Hg lower than that obtained by auscultation and considerably below the direct pressure—but no estimate of diastolic pressure. It is particularly unsatisfactory with infants and children because the pulse in their arms and legs is often difficult to feel.

For auscultation a stethoscope is placed over the artery immediately below the cuff. The cuff is inflated and deflated as for palpation until the pressure in the artery just

exceeds that in the cuff. When this point, the systolic pressure, is reached a tapping sound can be heard. With continued deflation the sound at first grows louder, then becomes dull and muffled, and eventually disappears in most adults. Neither muffling nor cessation of sounds is a very reliable index of diastolic pressure in children. Among 120 children aged 3 to 19 years examined by Moss and Adams (1963) only 67% had both sounds. No muffling could be heard in 16%, and muffling was not followed by complete cessation of sound in 27%. The correlations with direct measures were low (32-36) for both points. In general, muffling yielded estimates that were too high and complete cessation readings that were too low, but the variability was somewhat less for muffling.

Because all heart sounds are less easily discriminated in children, and because auscultation involves more cooperation from the subject than can regularly be expected of infants, Goldring and Wohltmann (1952) devised a variation called the "flush" technique. Sufficient pressure is applied to the hand to blanch the area without causing crying. A pressure cuff is then attached and inflated. Pressure on the hand is removed and the cuff slowly deflated. As soon as normal color (flush) appears, the pressure, which is then about midway between the systolic and diastolic pressure, is read. If the foot is used instead of the hand, the pressure is 5-10 mm Hg higher. In addition to yielding only a single value, the flush method may produce variable results, in part as a function of the speed of deflation and in part because of failure to recognize the first flush (Keith, Rowe, and Vlad, 1967; Moss and Adams, 1964).

Basically, the oscillometric method substitutes instrumental recording for palpation or listening for sounds, a definite asset in working with infants and children. The occluding cuff is placed on the arm or leg and manipulated as in auscultation. An oscillometer is applied at a lower point. While the pressure in the cuff is greater than the systolic pressure no blood flows, and hence no vibrations occur to be sensed by the oscillometer. In fact, there may be a few pulsations of small amplitude as the systolic pressure is approached, but when it is reached the ampli-

tude of the oscillations suddenly rises to about 3 mm in infants and 5-6 mm in older children. The point at which the pulsations become reduced again is the diastolic pressure. Additional advantages of oscillometry are readings close to those from direct measures and the fact that the cuffs can be attached but not inflated until after the infant goes to sleep. If automatic recording is incorporated into the system, repeated observations can be made with less stress for either infant or observer, and with less expenditure of the observer's time (Curiens, Brownell, and Aronov, 1957, Gupta and Scopes, 1965).

Similar advantages can be claimed for several other kinds of apparatus that have been introduced in research settings, such as a differential optical pulse indicator (Rice and Posener, 1959), a photocell oscillometer (Goodman, Cumming, and Rabe, 1962), and plethysmographs (Celandier and Thunel, 1960, Kailberg, Moore, and Oliver, 1965, Levison, Kidd, Gemmell, and Swyer, 1966, Schaffer, 1955), all of which record vibrations passing beyond the site of pressure, and a microphone placed beneath the occluding cuff (Moise, Brownell, and Curiens, 1960). On the other hand, it is fairly difficult to keep a plethysmographic system leak-proof, and anything greater than minor movements will cause artifacts in almost any automatic recording.

At best, even reasonably reliable measures, particularly from infants and young children, demand much attention to procedural detail. Largely for this reason, assessments of blood pressure, although theoretically important, are rare in developmental psychophysiological studies. Basal measures in adults are taken 10 to 12 hours after the last meal and following a 30-minute rest. No young infant would be in normal condition if deprived of food for so long a time, and unless sleep occurs spontaneously or is induced, only the most ingenious experimenter will have a relaxed rather than an active subject at the end of an idle half hour. Standard, as contrasted with basal conditions are less stringent, measurements being made after an interval of rest and no sooner than two hours after eating.

Activity, emotional upset, and variations in respiration all influence blood pressure.

Even in newborns, for example, crying will increase the systolic pressure by 30 mm Hg or more (Gupta and Scopes, 1965, Woodbury, Robinow, and Hamilton, 1938, Young and Holland, 1958). Raising a young infant's head or holding him in a sitting position elevates the arterial pressure (Gupta and Scopes, 1965). In infants less than 24 hours old, Gupta and Scopes (1965) also observed increments in directly recorded pressures of as much as 20 mm Hg during sucking, whether or not food was ingested. After sucking ceased, pressures returned to resting levels, stayed constant for 30 to 60 minutes, and then declined markedly if the infant fell into a deep sleep. "As the child emerges from this deep phase of sleep the blood pressure again rises to approximately the resting level" (Gupta and Scopes, 1965, p. 639). Many investigators prefer postprandial conditions for infants, but the findings just cited indicate that the values recorded will vary with the state of the child.

Unlike some other physiological measures, blood pressure does not seem to be affected by moderate changes in environmental temperature in either premature or full-term infants (Contis and Lind, 1963, Gupta and Scopes, 1965, Levison, Kidd, Gemmell, and Swyer, 1966) or older children and adolescents (McKee and Eichorn, 1953). Gupta and Scopes also found no evidence of diurnal rhythms in young infants.

Especially in infants and young children, inappropriate cuff size is a major source of error. A cuff that is too narrow relative to the length of the limb yields measures that are too high, because greater inflation pressure is needed to compensate for the reduced compression of the artery. Conversely, too wide a cuff may give readings that are too low. When a longer portion of the artery is compressed, resistance increases, decreasing the blood flow. Hence the pulse may disappear before reaching the far end of the cuff. The most widely recommended criterion for cuff width is a size about two-thirds the length of the segment of the limb to which it is attached (Keith, Rowe, and Vlad, 1967, Watson and Lowrey, 1967).

From simultaneous comparisons of auscultatory and intraarterial pressures in 128 children 3 to 19 years old, Moss and Adams (1965) report that cuff widths of 5 cm

at 3 to 5 years, 7 cm from 5 to 8, 9.5 cm from 8 to 14, and 12 cm after 14 produce systolic pressures that do not differ by more than 8 mm Hg from direct measures. These sizes are slightly smaller than those that Keith, Rowe, and Vlad (1967) have found to agree well with direct recordings: 3 cm for prematures, 4.5 cm for full-term to 2 years, 7 cm for 2 to 4 years, 10 cm for 5 to 9 years, and 13 cm for 10 to 14 years. Except for the larger sizes suggested for children under 4 by these authors, their standards are similar to the widths recommended by the American Heart Association Committee on Blood Pressure (Bordley, Connor, Hamilton, Keil, and Wiggers, 1951). However, the proper size to use with young infants groups is still a matter of controversy.

Since 1938, when Woodbury, Robinow, and Hamilton reported that only a 2.5 cm cuff gave readings that closely paralleled direct ones, this size has been widely adopted. On the other hand, Schaffer's (1955) repeated assessments on infants during their first day with 2.5, 4, and 8 cm cuffs and an impedance plethysmograph and electric manometer showed the narrow, short cuff (2.5 × 4 cm) to yield unreliable results and probably spuriously high ones, at least with sensitive recording apparatus. Reinhold and Pym (1955) also considered measures made with a 2.5 cm cuff to be more variable than those done with a 6 cm cuff, but the mean systolic pressure of about 50 mm Hg obtained with the latter in infants 1 to 3 days old is very low compared to most direct readings. Recording with a photocell oscilloscope in a small group of infants aged 1 week to 30 months, Goodman, Cumming, and Raber (1962) got close agreement with intra-arterial pressures and among each other for cuff widths varying from 2 to 3.7 cm. A sharp drop in levels was observed when a 6.5 cm width was used.

On the basis of a study with children aged 1 day to 4 years, Moss and Adams (1964) concluded that cuff size was not so important with the flush method. Mean pressures were lower the larger the cuff, but the differences among cuffs of 5, 9, and 12 cm were not statistically significant. Several other investigations do suggest that in newborns the most stable results with this method are

achieved with a 4 cm cuff (see review in Young, 1961).

How great the methodological differences in recorded arterial pressures are relative to age changes can be inferred from the data assembled in Tables 2, 3, and 4. Omitted from these tables are studies in which subjects were grouped over a wide time span for the particular ages concerned, for example, several days in the case of newborns, in which the recording technique was not constant, or in which age or cuff size was not specified. To provide illustrations of flush values through most of the first year an exception to the cuff width criterion, which does not seem to be a major one for this technique, was made for the data from Watson and Lowrey (1967). Research on older children was not included if pressures were reported for only one sex or for the sexes combined.

Regardless of technique, and despite the great variability among young subjects, most studies show the early weeks and months to be a period of comparatively rapid increase in pressure. Yet the values obtained vary so widely with method that were data collected with different methods (or with the same technique but a different cuff size) to be utilized for establishing age trends, the latter could be obliterated or even inverted. Of course, flush pressure is intermediate between the systolic and diastolic levels and so would be expected to differ from those values as assessed by any means. When measures are made by other indirect methods, cuff size is in general more influential than recording technique in determining the absolute values observed during infancy and early childhood. Pressures taken with a cuff of 4 or 5 cm within the first few days of life range between the mid-forties and low sixties, with an average in the mid-fifties. Higher levels, closer to intraarterial pressures, are characteristic with narrower cuffs.

Additional sources of variation during the early days are time elapsed since delivery, time of clamping of the umbilical cord, mode of delivery, and degree of asphyxiation. Ashworth and Neligan (1959) found the mean systolic pressure to drop abruptly from a high of 92 mm Hg during the first few minutes after birth to an average low of 60 four hours later in normal infants whose cords

^a Means for both systolic and diastolic pressures are listed where available. Some means were read from authors' graphs or computed from their data.

^b Ranges on Day 1 indicate means obtained at different times during the first 24 hours.

were clamped early. If clamping was delayed, so also was the decrement, but it occurred within the first 24 hours. Regardless of time of clamping, a steady rise ensued throughout the remainder of the first week, but during the second day pressures never exceeded those recorded immediately after delivery. In another study (Goodman, Cumming, and Raber, 1962) the mean fall in pressure was marked but smaller, 20 mm Hg, and the minimum was reached on the average at two hours instead of four. The following

rise was very gradual during the rest of the first day and steeper thereafter, birth levels being regained by the fourth day. Infants delivered by caesarian section have lower systolic pressures than normal vaginal births (Holland and Young, 1956; Neligan, 1959), whereas respiratory distress may raise (Neligan, 1959) or lower (Gupta and Scopes, 1965; Holland and Young, 1956) the blood pressure.

Such information as has been secured on blood pressures during human gestation

comes from measures made at or after delivery on premature infants. Therefore, interpretations must be tempered not only by the possibility of abnormalities in the subjects and differences between extrauterine and intrauterine environments, but also by a number of the methodological factors mentioned earlier, such as time since delivery and treatment of the cord. Probably the most definitive data are those reported several decades ago by Woodbury, Robinow, and Hamilton (1938). Recording directly from a cannula in the umbilical artery at delivery, they obtained pressures of 33-39/21, 55/25, 70/35, 85/45, and 80/46 at 5, 6, 5, 7, 8, and 9 fetal months, respectively.

Most subsequent investigators have been concerned with methodological issues (Kafka,

1967), reflexes (Moss, Duffie, and Emmanouilides, 1963, Young and Holland, 1958), or the effect of birth weight (Bucci, Scalmandre, and Savignoni, 1963, Levison, Kidd, Gemmell, and Swyer, 1966) or various disorders (Gupta and Scopes, 1965, Neligan, 1959, Neligan and Smith, 1960), and only a few have categorized their subjects by gestational age. Rarely have infants that could be considered to be younger than 7 fetal months been included. Despite the limitations of individual studies and variations from study to study in the absolute levels recorded, most of the accumulated data support the conclusion that pressures are lower in prematures than in normal full-term infants and probably increase at least until the eighth prenatal month. In all other species that have

been examined blood pressure rises during gestation, but there is considerable variability in pattern of increments (Dawes, 1961)

Whether age or weight is the more important factor cannot be stated conclusively, but the evidence for man tends to favor weight. Goodman et al (1962) worked with infants of 23-36 weeks gestational age as well as with full-term babies. Systolic pressures in the premature were correlated with both weight and age, increasing to the thirty-second fetal week. Among infants born at 27 to 34 weeks, Levison and his associates (1966) found no systematic variation of systolic pressure with gestational age. Nor was there any difference in pressures between infants weighing 500-1000 grams and those

of 1000-1500 grams. However, pressures rose linearly with weight above the latter size. Similarly, Bowman's (1933) data reveal very little difference in either systolic or diastolic pressure on the fourth day of life between infants weighing 2-3 or 3-4 pounds, but systolic pressures were higher and equal in the 4-5 and 5-6 pound groups and slightly greater in infants of 6-7 pounds. In contrast, Gupta and Scopes (1965) observed no differences in pressures during the first 6 hours after delivery between a group weighing over 2500 grams at birth and one with birth weights of 1501 and 2500 grams, levels were somewhat lower in infants whose birth weights were less than 1500 grams. These subjects had various disorders or were "nor-

Table 4 Age and Sex Norms for Diastolic Blood Pressure

[illegible]

mal" but small for gestational age and were examined under a variety of circumstances. No real trend with weight is discernible in the few premature (defined as a birth weight of less than 2.5 kg) infants studied by Holland and Young (1956).

Circulatory and respiratory adjustment to extrauterine life only briefly reverse the rising trend of blood pressure which apparently begins early in gestation and continues at varying rates throughout the rest of the life span. Judging by the values derived by most investigators, the increase in systolic pressure is in the neighborhood of 20 mm Hg between the first day and the fifth to tenth, and a major part of it may represent a return to birth levels. Some 3 to 9 more months are required to achieve another rise of about equal magnitude. The negatively accelerated rate of increase is even more clearly seen in the fact that 15 to 20 years pass before a comparable or somewhat smaller increment has taken place.

Because the development of diastolic pressure has been less thoroughly documented, particularly during infancy, generalizations must be somewhat more tentative and imprecise. By combining figures from different studies an increase of about 15–20 mm Hg between the first few days and the third to fifth year may be inferred. A further rise of 10–15 mm Hg, largely within the next decade, can be observed in data for the sexes separately (Lincoln, 1928; Londe, 1966; Richey, 1931; Shock, 1944; Stocks, Stocks, and Kain, 1927), girls only (Burlage, 1923; Nylin, 1935; Schwenk, Eggeis-Hohmann, and Gensch, 1955), boys only (Hahn, 1952; Schwartz, Britten, and Thompson, 1928), and mixed sex groups (Faber and James, 1921; Graham, Hines, and Gage, 1945).

Except for the work of Sundal (1929), which is based on palpation, research on age changes after the first year or so has been done by auscultation. Pressure standards across age have yet to be established by direct recording, although some information may be gleaned from comparative plots of auscultatory and direct measures (Moss and Adams, 1963, 1965). Beyond late childhood normative data have almost always been obtained with a cuff 12 to 13 cm in width—Lincoln's (1928) was 9.5 cm. Thus at older ages differences among studies in

pressure levels stem primarily from situational factors other than recording technique or cuff size. Shock (1944) secured the only truly basal measures. Practiced subjects do not account for the comparatively low norms from his longitudinal study, because equal levels characterized controls put through the same procedures at just one age.

Although the subjects in the studies of Lincoln (1928), Richey (1931), and Sundal (1929) were not in a basal state, the conditions were good, in that measurements were semilongitudinal, were made chiefly in the morning, and the children were in settings with which they were familiar. As already noted, Sundal also used palpation, a method which typically gives values 2–5 mm lower than does auscultation. Blood pressures about as low as those in the four studies previously cited have been reported by Nylin (1935) from a study of various physiological functions in a small group of girls aged 10 to 15 years, for girls 3 to 16 years old (Downing, 1947), males aged 4 to 49 (Schwartz, Britten, and Thompson, 1928), and the sexes combined (Faber and James, 1921). Despite the care with which Londe (1966) made his determinations, they were taken in the course of routine physical examinations in a physician's office or a pediatric clinic and reflect the higher levels to be expected in such situations. Like pressures have been obtained under rather comparable circumstances by Burlage (1923) and Schwenk, Eggeis-Hohmann, and Gensch (1955) in girls, Hahn (1952) in boys, for the sexes combined by Graham, Hines, and Gage (1945), and in each sex by Stocks, Stocks, and Kain (1927).

Again, were values derived in different situations to be combined to form age curves, the increase seen in separate studies during childhood and adolescence could be obliterated. Only in Shock's (1944) data is a small and temporary reversal of the upward trend in diastolic pressure between 12 and 14½ years evident. He suggests that so slight a decrease may be masked in cross-sectional observations, but his basal conditions may also have helped to reveal this digression. Further, the sex difference that develops in adolescence is not readily apparent, at least in its earlier phases, unless pressures are de-

terminated under carefully controlled conditions

Of the two major factors governing blood pressure, peripheral resistance may reasonably be assumed to be more influential than cardiac output in producing developmental changes. Data indicative of a decline in cardiac output with age have already been summarized. A countercourse for peripheral resistance is evidenced by a rate of blood flow through the limbs of infants about twice that of adults (Celander, 1966, Celander and Thunell, 1961, Kidd, Levison, Gemmell, Aharon, and Swyer, 1966), for blood flow is inversely proportional to resistance. Noting these trends, Young (1961, 1966) proposes limited peripheral resistance as the primary cause of low arterial pressure among infants. She hypothesizes that resistance is restricted by inadequate vasoconstriction resulting from some deficiency in the tonic activity of neural and chemical mechanisms regulating blood flow through channels other than those to the skin. Within a few days after birth the vasomotor tone of skin vessels over the entire surface of the infant seems about equivalent to that in the adult (Bower, 1954, Bruck, Bruck, and Lemtis, 1957, Young, 1962, Young and Cottom, 1966). However, these vessels are thought not to be involved in the control of pressure through the redistribution of blood.

Also cited by Young (1961) as a partial explanation of the brief postnatal drop in pressure are observations suggesting that peripheral resistance declines because asphyxia renders the vasomotor centers and blood vessels even less responsive. Individual differences in the duration and degree of asphyxia and in the distribution of body fluids brought about by forces exerted on the fetus during labor are advanced as possible sources of the wide variation in blood pressure among newborns. According to several authorities, the brief decrement in pressure after delivery may be precipitated by expansion of the pulmonary and intestinal vascular beds and a decline in plasma volume (Conitts and Lind, 1963, Lipton, Steinschneider, and Richmond, 1965).

In all likelihood, degenerative as well as maturational changes underlie increases in peripheral resistance with age. The rising trend in blood pressure among older persons

has for many years been attributed to decreasing distensibility and hence greater resistance of the arterial walls consequent upon atherosclerotic lesions. There is also good reason to believe that fatty streaks begin to infiltrate the vasculature during childhood, sometimes as early as the first year (see review in Geisten, 1964).

That increment in cardiac output may play a role in at least one aspect of developmental change in blood pressure is implicit in Tanner's (1962) rationale for the appearance of a sex difference during adolescence. He states that "establishment of a greater basal stroke volume at adolescence (Nylm, 1935), coincident with the greater increase in heart size" and perhaps supplemented by an increased blood volume, is probably responsible for the higher pressures of males. Cardiac output is a multiplicative function of stroke volume and heart rate, blood volume and heart size are two determinants of stroke volume.

Age, physiological maturity (as measured by skeletal age, menarcheal age, age at maximum growth in height, or age at reaching successive stages of secondary sexual characteristics), weight, height, and the levels of various physiological parameters are all to some degree intercorrelated (Nicholson and Hanley, 1953, Shock, 1943, 1944, Tanner, 1962). Which of the first four factors are most closely associated with blood pressure cannot yet be decided. When systolic pressure is examined in relation to menarcheal age, it is found to reach a peak before menarche and then to decline gradually for several years (Shock, 1943). Early maturing girls (Schwenk, Eggers-Hohmann, and Gensch, 1955, Shock, 1944) and boys (Shock, 1944) develop higher systolic and diastolic pressure sooner than do late maturers. At the same time, the early maturing are also heavier and taller. Hypertension is more common among obese adults than the underweight or those of appropriate weight for height. Among children the evidence is less conclusive.

In very young normal and premature infants positive associations of blood pressure with both weight and postnatal age have been reported, but their statistical significance was not tested (Forfar and Kibel, 1956, Levison, Kidd, Gemmell, and Swyer, 1966). Positive although insignificant corre-

lations with weight exist in Allen-Williams' (1945) measures on boys and girls aged 6 months to 5 years. Londe (1966) found systolic pressure to be significantly correlated with weight in both sexes at most ages from 4 to 15 years. The coefficients for height were lower and insignificant. Generally low, positive associations obtained between diastolic pressure and weight and height, but only those with weight in girls approached significance. On the other hand, Richey's (1931) data show significant correlations from age 5 to 19 years between weight and diastolic as well as systolic pressure for each sex and between diastolic pressure and height for girls. Height also influenced systolic pressure in girls 11 to 15 years old and boys over 10. For his sample of boys aged 11 to 15 years Hahn (1952) states that blood pressure is more highly correlated with weight, surface area, and height than with age, and the correlation was stronger for the first two variables. However, the figures he presents do not seem to justify the latter claim. Stocks and Karn (1924) also demonstrated an association between systolic pressure and both weight and height and between diastolic pressure and height in boys aged 9 to 15 years.

A related question of concern is the predictability of hypertension. Prompted by evidence that elevated resting pressures were prognostic of later disease in young adults (Diehl and Hesdorffer, 1933; Levv, Hillman, and Stoud, 1944), Harris (1958) examined blood pressure records on subjects in a longitudinal study. Two groups of 24 boys each and two of 20 girls each were selected from the total sample on the basis of having the highest and lowest blood pressure for their sex at 15, 16, and 17 years. Plots of systolic and diastolic levels beginning at age 5 showed these subgroups already to be well separated by that age. Unfortunately, possible causal associations could not be ascertained because the "highs" of both sexes were early maturers as well as more mesomorphic or endomorphic, and no history of cardiovascular dysfunction in the "highs" at any age was presented.

If blood pressure responses to stress are more reproducible than resting levels, as some research indicates (Lacey and Lacey, 1958, 1962; Sontag, 1958; Tanner, 1958) then they may also be more effective in the

prognosis of cardiovascular disease. A unique pair of studies utilizing the cold pressor test illustrates the potential of this approach. In the first study Hines (1937) examined 400 children 6 to 18 years old. Subjects plunged one hand up to the wrist in water of 4° C and held it there for one minute. The reflex rise in blood pressure was recorded from the opposite arm. After reevaluation of 207 members of the original sample 27 years later Barnett, Hines, Schinger, and Gage (1963) reported that both responsiveness to the imposed stress and hypertension were predictable from the earlier measures.

Electrocardiogram

To differentiate the electrocardiogram from the electrocorticogram (a recording from the cerebral cortex) the original abbreviation, EKG, from the German spelling, is preferable to ECG. The EKG is a record of the electrical field effects generated by the action potentials of the nerve fibers of many cardiac muscle cells. From it may be determined the site of the pacemaker, conduction routes, and the rate, rhythmicity, patterns of excitability and refractoriness, and electrical axis of the heart. A large body of empirical data relating abnormalities in these characteristics to various cardiac disorders has been accumulated.

For the standard limb leads used in electrocardiography since the turn of the century surface electrodes are placed on each arm and on the left leg. Bipolar recordings (i.e., those obtained between two active electrodes) are made between the two arms (lead I), the right arm and left leg (lead II), and the left arm and leg (lead III). Illustrated in Fig. 3 are the typical pattern of deflections derived from lead II in a normal adult and the intervals of the cardiac cycle usually included in an analysis of the EKG. Other parameters regularly of interest are the duration, direction, amplitude, and shape of P, Q, R, S, and T waves.

The P wave arises from atrial depolarization initiated by the spread of excitation originating in the sinus node. After a brief isoelectric period throughout the heart, the ventricles become depolarized, producing the QRS complex. Included in the P-R interval is the time required for the excitation wave to depolarize some of the atrial muscles

Fig 3 Fiftieth percentiles for EKG intervals (in minutes) Redrawn from McCammon (1961)

and pass down through the atrioventricular node and the bundles of fibers which carry impulses to the ventricular muscle. The T wave reflects ventricular repolarization, atrial repolarization is generally masked by the QRS complex. Continuing ventricular depolarization and perhaps some slight beginning repolarization occurs during the S-T segment. Subsequent to the T wave, a U wave, thought to be produced by slow repolarization of the papillary muscles projecting from the walls of the ventricles, is sometimes observed. There is often some variation among the three leads in the amplitude and duration of waves and the length of intervals.

Current clinical routine also calls for at least nine other tracings, six from the chest (precordial leads) and three from the limbs. Although the different "views" provided by additional leads are very useful in the diagnosis of pathology, more normative material indicating something about the maturation of cardiac function and understandable by persons without extensive background in EKG analysis are derived from the standard limb leads. Further, the only developmental data on the EKG of the fetus *in utero* are based on records that closely resemble the

configurations observed postnatally in these leads.

Quite by accident Cremer (1906) picked up the EKG of a fetus near term while recording that of the mother with standard limb leads and a string galvanometer. Using the electrodes attached to the surface of the maternal abdomen and a standard EKG machine, a number of subsequent investigators had good success in deliberate attempts to duplicate his feat (see summary bibliographic table in Bernstein and Borkowski, 1955). At least during the latter part of gestation such simple apparatus suffices in a large proportion of cases to demonstrate the existence of a living fetus and to provide tracings from which manual counts of fetal heart rate can be made. Southern (1954) was even able to measure amplitudes and durations. If EKG's of this caliber are to be secured with any degree of regularity, however, better instrumentation is required to overcome the impediments to *in utero* recording.

Amniotic fluid and maternal tissue attenuate the weak signal produced by the fetal heart. Further insulation against the transmission of impulses seems to be added, particularly in the seventh and eighth months, by the fetal coating of vernix caseosa, an oily

secretion containing discarded skin cells (Goodyer, 1942, Wimmer, 1954). Except under a few special circumstances mentioned later, potential size per se does not now constitute a major restriction on the quality of intrauterine EKGs. Adequate amplification is supplied by electroencephalographs or high-sensitivity fetal electrocardiographs. Getting an input that is sufficiently free of artifacts is another matter. The "noise" from fetal or maternal muscles, the mother's heart beat, or alternating current in the environment may be great enough to obscure any fetal EKG. On the other hand, relatively little noise will interfere with a low level potential.

Unless a satisfactory signal to noise ratio can be achieved, automated heart rate counts (see following section, Heart Rate) and analyzable EKG configurations are precluded. Some means must be found to increase the fetal potential without simultaneously enhancing the artifacts, or to reduce the interference, or both. At times the signal reaching the surface is so small or the artifacts are so strong that closer electrode contact with the fetus than is possible with abdominal or limb leads is the only solution. Such small signals may arise, for example, in early gestation, polyhydramnios (excessive amniotic fluid), or maternal obesity; strong artifacts are characteristic of labor, when the potentials generated by uterine contractions are especially powerful. Establishing direct contact maximizes the fetal signal, essentially eliminates the maternal EKG, and materially decreases the noise from most other sources.

One approach is to insert fine electrodes through the abdominal wall and under the skin of the fetus (Caldeyro-Barcia, Poseno, Pantle, Negreiros, Gomez-Rogers, Faundes, Henry, Zambrana, Arellano, Fillea, and Cabot, 1961). After the cervix is dilated and the membranes ruptured, a flexible rod electrode, insulated except at the tip, can be introduced into the uterus via the cervix until it touches the fetus (Hon, 1959, Smyth, 1953, Sureau, 1956). Alternatively, an electrode may be attached to the presenting part of the fetus (Hon, 1967). For close but indirect contact during early pregnancy Bernstein (1961) recommends vaginal leads, a collar electrode fitted about the cervix, or an electrode clamped to the cervix.

Asepsis must be maintained while employing any of the electrodes described above. Because surface abdominal leads are easier to apply and involve no risk, they are still favored whenever recording conditions are, or can be made, suitable. By a combination of procedures an acceptable signal to noise ratio can be effected in most situations, and sometimes even during labor (Larks and Larks, 1965). Many of the basic precautions are those regularly observed in electroencephalography, where surface potentials are very small and artifacts from muscle, the EKG, and electrical noise also a problem.

As instrumentation and techniques have improved, the utility of fetal electrocardiography as an obstetric and research tool has become more extensive (Bernstine, 1961, Cameron, 1967, Kendall, Farrell, and Kane, 1964, Larks and Larks, 1966). Not only can the presence of a fetus, multiple conceptions, and type of presentation (say, occipital or breech) be determined without the hazards of radiography, but evidence of viability can also be obtained. Monitoring high-risk pregnancies and deliveries by electrocardiography is feasible when other methods, such as listening for fetal heart sounds or biochemical assays of the oxygen, carbon dioxide, and acid content of the blood, are not. Blood samples cannot be taken until after the onset of labor, whereas detection of fetal heart sounds is rarely possible in the same circumstances that require special electrocardiographic procedures, for example, early gestation, polyhydramnios, and labor. Yet these are the conditions in which assessment of fetal status may be most needed. Only when the EKG is used to trigger a cardiometer (see Heart Rate section to follow) can the rapid changes in rate which occur in response to changes in intrauterine pressures, oxygen levels, and the like be fully appreciated.

In general, intrauterine EKGs give a more accurate picture of normal development than do those obtained from extubated fetuses. The premature often are not healthy specimens, and their heart rates may be slowed by anoxia or cooling subsequent to delivery. However, abortuses have furnished the earliest records of the human EKG. The QRS complex and T wave were detectable in a tracing from the heart of a 6 mm embryo.

(Marcel and Exchaquet, 1938), a length that is reached just about at the age (30 days or slightly younger) when the primitive heart tubes fuse and the complete EKG should theoretically first be present. Other direct recordings made as early as the sixth to tenth week indicate that a fully differentiated EKG is already present by these ages (Boikowski and Bernstine, 1955, Goodver, 1942, Heard, Bulkley, and Schaefer, 1936, Lind, Stein, and Wegelius, 1964). By about 11 weeks *in utero* records can be reliably obtained, although auscultation of fetal heart sounds is not possible until about the eighteenth week (Mattingly and Larks, 1963).

When the subjects are in good physiological condition the heart rates observed early in gestation are as rapid as or somewhat higher than is typical of the neonate at rest or in a state of minimal metabolism. If the pulse is faster, one would expect the intervals of the cardiac cycle to be shorter, and they seem to be. Some of the best supporting data comes from studies done in Sweden on fetuses aged 10 or 12 to 25 weeks delivered by caesarian section at legal abortions (Lind, Stein, and Wegelius, 1964). Before the fetus was removed from the uterus and while the placenta was in place, the placental circulation intact, cord color and pulsations good, EKGs were obtained. The investigators concluded that the P-Q, QRS, and Q-T segments were probably somewhat shorter than in the full-term newborn, but, because the size of the heart was so small at these ages, the absolute speed at which excitation spread through the heart was considerably slower. Smaller heart size and less well developed muscle probably also account for the lower amplitudes of these EKGs, for attenuation obviously is not a factor in direct fetal recording.

Aside from these differences in amplitude and conduction times, fetal EKGs resemble neonatal ones in showing right ventricular preponderance and aberrations of the T wave. The amplitudes of QRS complex recorded from midline abdominal leads before delivery are correlated with those obtained in lead II after delivery in the same infants (Larks and Larks, 1966). Correlations for the R and S waves were significant and moderate (6) and for the Q wave, which is more difficult to record and measure, signifi-

cant but low (3). In addition, the calculated electrical axes had similar prenatal and postnatal means and were highly correlated (79). A previous study (Larks and Larks, 1965) established a normal range for axis deviations and related abnormalities to complications of gestation and delivery. During normal labor changes in pressure in the umbilical artery resulting from cord compression by uterine contractions have sometimes been found to produce marked changes not only in the QRS complex but also in the P wave and the ST segment (Hon, 1966).

Methodological difficulties do not disappear once the infant becomes accessible. Overriding of the P wave of one cardiac cycle by the T wave of the preceding one is the most frequent problem, because while the heart rate is rapid there is almost no T-P interval (the period during which all chambers of the heart are in diastole). Movement artifacts are if anything more troublesome when the limb leads are on the infant himself. Chest leads are much less susceptible to interference from movement, but unless small electrodes are used and care is exercised in applying and removing electrode paste electrical phantoms will be recorded (McNamara, 1964, Ziegler, 1951). With telemeters or portable, battery-operated tape recorders long-term recording on a moving subject can be made quite successfully (Morgan, Deane, and Guntheroth, 1965). Fortunately, prior ingestion of food has no consistent effect in infants and children despite frequent reports of postprandial changes in adults (Gooch, Mintz, and Nova, 1967).

Associated with the hemodynamic, and probably also the respiratory, metabolic, and electrolytic transitions of the first week or so after birth are a succession of alterations in the EKG. The time at which the cord is clamped seems to have little influence (Buckels and Usher, 1965). However, rather precise knowledge of the time that has elapsed since delivery is essential for evaluation of the normality of the EKG of the newborn, for Walsh's (1963a, 1963b, 1963c, 1964, 1966) serial examinations of full-term and premature infants show that shifts occur with great rapidity during the first few hours following delivery. Within 30 to 60 minutes the P wave and all intervals are prolonged. The amplitude of the QRS complex is in-

creased, particularly in chest leads representing right ventricular activation, Q waves are absent in left precordial leads, but good-sized, positive T waves appear in all chest leads. A few hours later the duration of the P wave, which was primarily responsible for the lengthened P-R interval, and of the P-R and QRS segments are considerably decreased, the voltage of the R and S waves is reduced in most chest leads, Q waves are found in one (V_6), and the T waves are positive in the right but negative or absent in the left chest leads. Further contrast among leads in the incidence and amplitude of the Q, R, S, and T waves, apparent on the second and third days, continue to develop through the end of the first week. By this time the Q-T interval has shortened significantly, the decrease being most notable between the third to the fifth or sixth days.

"Intervals which reflect atrial and atrio-ventricular conduction show relatively little change after the first hour of life, whereas those which involve ventricular conduction are not only influenced by events attending birth, but also by those affecting the first few months of life" (Walsh, 1964, p. 190). Lengthened P waves often characterize enlargement of the left atrium (Walsh, 1966). Left to right shunting through the ductus arteriosus in the course of the transition from the fetal to postnatal circulation increases the load on the left heart during diastole. Further, vagal activity may bring about the temporary postnatal slowing of the P-R and QRS segments and increased voltage of the QRS, and the responsiveness of the heart to vagal control may be heightened because the oxygen content of the blood, reduced during delivery, stays low for about the first hour (Walsh, 1966).

Although Ziegler (1951) accounted for the decrement in the Q-T interval in terms of the concomitant increase in pulse rate (the duration of Q-T is negatively correlated with heart rate at all ages), Walsh (1964) points out that neither in his data nor in Ziegler's is the reduction in Q-T per unit change in heart rate anywhere nearly sufficient to produce the observed decrease in Q-T time. Nor did Ziegler find the length of QRS or Q-T to be effected by heart volume (1963a), as others have thought it to be (Wilson and Herrmann, 1930). The likelihood remains,

however, that the length of Q-R and the amplitude of the R wave are related to some degree to the *relative* thickness of the walls of the ventricles (Emery and Mithal, 1961, Keen, 1955, Sodi-Pallares, Portillo, Cisneros, De La Cruz, and Acosta, 1958, Walsh, 1963c). Compared to the T wave, the QRS complex is quite stable, especially after the early neonatal period. Ziegler (1966) attributes this greater stability to the fact that anatomic factors largely govern the QRS complex, whereas the T wave is much more dependent on functional variables. For example, abnormalities of the T wave or the Q-T interval tend to occur in disturbances of electrolyte (especially potassium and calcium) or acid-base balance (Keith, Rowe, and Vlad, 1967, McNamara, 1964).

All investigators have described peculiarities of the T wave and right ventricular preponderance as the most outstanding features of the neonatal EKG. Of particular interest is the fact that by such criteria as ventricular weight, thickness of the ventricle walls, or heart volume the left ventricle is better developed than the right at the end of the first month or sooner (Emery and Mithal, 1961, Keen, 1955, Kjellberg, Rudhe, and Zetterstrom, 1954, Lind, 1950, Lind and Wegelius, 1954, Patten, 1933, Scammon, 1923, Sodi-Pallares et al., 1958), yet electrical right ventricular dominance persists for several months. Before birth resistance to flow is high in the lungs, and the right ventricle pumps against this resistance and that of the systemic circulation (via the ductus arteriosus). As the pulmonary resistance begins to drop shortly after delivery and shunting declines, the work of the right ventricle decreases even though it pumps about as much blood as the left. On the other hand, with increasing age, resistance in the systemic circulation rises, so the work of the left ventricle becomes greater.

Walsh's (1964, 1966) comparisons of healthy premature and full-term infants reveal the role of postnatal experience with changed work loads in the gradual development of left ventricular dominance. Two groups of prematures differing in age (44 versus 90 days) and hence weight were matched by weight with two groups of full-term infants. To achieve a weight match the latter were, of course, younger (about $5\frac{1}{2}$

days) in terms of postdelivery age. The EKGs of the premature, who, although younger on a gestational age basis, had circulatory systems that had operated longer in the postnatal fashion, showed more evidence of left ventricular preponderance. Differences between premature and full-term infants in most characteristics of the EKG were marked only in the first week or two. Nevertheless, some other factors, maturational and/or experiential, must influence the cardiac reactions represented in the EKG, because, despite equal heart rates in all groups, the Q-R, QRS, and Q-T intervals were significantly longer among the full-term infants, and the P-R duration and P amplitude tended to be greater.

Beyond early infancy the rate of change in parameters of the EKG becomes much slower. So slight are the shifts in amplitude that when mentioned at all in normative material the maximum for healthy individuals of a wide age range is usually all that is given. For example, the P wave is generally said not to exceed 2.5 mm up to 1 year nor 3 mm between 1 and 14 years (Keith, Rowe, and Vlad, 1967). By convention, 1 cm of deflection equals 1 mv. Throughout life the T wave continues to be the most labile of the EKG configurations, and it is the most delayed in reaching the adult pattern. Not until 16 years can the T wave in the first chest lead be expected to be upright in most members of a normal population, although it may be so by 12 years in a sizable number (Keith, Rowe, and Vlad, 1967, Sodi-Pallares et al, 1958, Ziegler, 1951).

Standards for interval durations are sometimes also stated simply as normal maxima over a fairly wide age span (Epstein, 1948, Keith, Rowe, and Vlad, 1967, Kossman, 1953), but averages and/or ranges for more restricted age groups are available (Burnett and Taylor, 1936, Hafkesbong, Diawe, and Ashman, 1937, Seham and Moss, 1942, Sodi-Pallares et al, 1958, Ziegler, 1951). Unique among the latter both for their detail and for the nature of the sample from which they are drawn are the norms reported by McCammon (1961). The minima, maxima, and tenth, twenty-fifth, fiftieth, seventy-fifth, and ninetieth percentiles for the P-R, QRS, and Q-T intervals in each of the three

standard limb leads are tabulated by month from 1 through 6 months, at 3 months intervals from 9 months through 14 years, at 14½ years, and yearly from 15 through 24 years. Variations from the stated ages were not more than 1 week before 3 years, 2 weeks from 3 to 10 years, and 1 month after that age. Included in the analysis were 4993 records on 214 healthy upper-middle class subjects followed for periods varying from 6 months to over 24 years. Except for a few studies in early infancy, these are the only longitudinal data of this kind on normal subjects.

Figure 3 combines the medians for boys from Lead II for the three intervals measured by McCammon. Even such major segments of the cardiac cycle last only tenths or hundredths of a second, so the average increase from age to age across such short time spans are only thousandths of a second and are far exceeded by the range at any one age. Given the small size of the intervals and increments, irregularities in the curves would be expected. Nevertheless, the group tends to rise steeply for all three intervals during the first six to nine months and much more gradually thereafter.

By 10 years the median for P-R is essentially at the adult level, with about half of the increment accomplished by 4 years. This interval also proved to be a very stable individual characteristic after the age of 2 years. Within any given year the values for a subject fluctuated very little, and his position in the group remained consistent across time. Exceptions were observed when a changing pacemaker was present, a phenomenon that occurred on several occasions in almost 25% of the children, primarily between the ages of 4 and 14 years. Contrary to the contention in almost all treatises on EKG development that the P-R interval varies directly with age and inversely with pulse rate, McCammon demonstrated that the association with heart rate is not linear.

Following a strategy previously used with adults (Schlamowitz, 1946), pulse rates and P-R durations were determined for a subsample before graded exercise on a bicycle ergometer and at 1-minute intervals for 5 minutes postexercise. As was true for adults, P-R duration did not vary systematically with pulse rate when age was thus held constant.

Graphs of the regular records also showed pulse rate to be very labile, while the length of the P-R segment for an individual was, as noted above, highly stable. The linear correlation between pulse rate and P-R was -0.1 . However, the plot suggested a curvilinear association, which was confirmed by a chi-square test. That is, there was a tendency for P-R to be shorter when the pulse rate was either very fast or very slow. McCammon speculates that both the P-R interval and pulse rate are a function of some other factor or factors, rather than having the direct and bifactorial dependence inferred heretofore.

Chest X-rays on these subjects also failed to verify the supposition of some investigators (Hafkesbrung, Drawe, and Ashman, 1937, Ahmuring and Massell, 1956) that increasing heart size underlies the prolongation of the P-R segment with age. Individuals with heart sizes much above or below the mean for age had P-R durations across the entire range of normal values. A priori this hypothesis is suspect, for the developmental curve for heart size follows the general growth curve for weight (Mareš, 1948), whereas that for the P-R interval levels off by about 10 years and has no adolescent spurt.

Marked sex differences and indications of an adolescent spurt were found in the QRS norms. The age curves at the ninetieth percentile closely resemble those for physical growth, but this pattern is increasingly attenuated as one moves down the percentile ranks. Probably because the termination of the QRS complex is difficult to determine precisely, intraindividual variations in its duration were quite large.

Although the length of the Q-T interval approximated the adult median by 10 to 12 years, a very slow increase was observed to the oldest ages included. A number of formulas have been devised for correcting Q-T for heart rate, and most involve a different constant for women than for men and children. In this sample the correlation between pulse rate and the length of Q-T was substantial (-0.59), but no sex differences were found until a correction was applied. After correction the Q-T duration was shorter in girls until they were about prepubertal. Then the sex difference reversed. McCammon com-

ments that the degree of separation of the sexes is surprising in view of the small differences in pulse rate. Correction for heart rate also eliminated age changes in the length of Q-T until adolescence, when a downward trend ensued. During this period the prolongation of the Q-T segment for some undetermined reason increasingly fails to keep pace with the decline in heart rate.

Not illustrated in the tables or graphs of any study is the dramatic increase in the T-P interval with increasing age and decreasing heart rate. Prolongation of the time during which all chambers of the heart are in diastole is greater on both an absolute and proportionate basis than for any other interval. At a heart rate of 150 beats per minute, which is typical of a 1-month-old infant while awake but not too active, the entire cardiac cycle takes 0.4 seconds. Only a little over 0.04 seconds is consumed by the T-P interval. The adult heart rate under similar conditions is about half as fast, and thus the cardiac cycle is twice as long. Yet the T-P segment is about 0.22 seconds, or over four times longer. Little hearts get little rest.

Heart Rate

Apart from their bearing on events occurring within the cardiac cycle, variations in heart rate among individuals or within the same individual during successive cycles are of inherent interest. Indeed, for both theoretical and pragmatic reasons, cardiac rate has been chosen more frequently than any other functional measure for psychophysiological research as well as for monitoring the condition of patients in clinical situations.

Heart rate is influenced by many aspects of mental and physical state, such as attention, emotion, pain, posture, exercise, digestion, respiration, oxygenation, metabolic rate, internal and external temperature, thyroxine, epinephrine, norepinephrine, and blood pressure. Such sensitivity to change in a wide variety of psychological, physiological, biochemical, and mechanical factors makes cardiac rate a useful response measure, but it also means that experimental conditions must be carefully controlled whether the effects of a particular variable are being explored or basal rates are sought. Despite the latter reservation, heart rate also offers practical advantages from the point of view of

measurement. It can be determined intermittently or continuously with relative ease by at least one of several methods even under circumstances where a full EKG, blood pressure, metabolic rate, or like measures are difficult or impossible to obtain or simply not applicable (e.g., respiratory rate during gestation.)

As for blood pressure, the oldest and still the most widely used techniques for obtaining heart rate are palpation and auscultation. Palpation is especially simple and convenient. If a finger is placed over a surface artery, pulsations are felt which arise from a sudden increase in the pressure and velocity of the blood generated by each contraction of the heart. In adults, pulse counts are usually taken at a radial (wrist) artery, but during infancy pulsations are often easier to feel over the carotid (side of the neck) or temporal (above and to the outer side of the eye) arteries. With certain exceptions already noted, auscultation of heart sounds through the maternal abdomen and hence rate counts can be accomplished by mid-gestation. After birth heart sounds can readily be heard through the chest wall, often without the aid of a stethoscope.

Maternal heart rate per minute by counting the pulse for 15 seconds and multiplying the result by 4. Given the lability of cardiac rate, however, particularly in the young, more representative and reliable values can be obtained by making counts for a full minute and repeating them at least twice. In some experimental situations brief intervals are deliberately examined to assess the degree of acceleration or deceleration occasioned by stimulation and the time required for recovery. For such work continuous, automatic recording is highly desirable, and instantaneous (beat-by-beat) rates cannot be secured in any other way.

Both instantaneous and average rates can be determined from any time-calibrated recording that contains a signal corresponding to a regularly recurring element of the cardiac cycle. Besides the action potentials from which the EKG is derived, mechanical displacements generated by the activity of the heart can be utilized as input. Over half a century ago Canestrini (1913) used a pneu-

It is common in clinical practice to esti-

mograph placed over the anterior fontanel to pick up the vibrations of the pulse wave and a system of levers to transduce them for kymographic (smoked drum) recording. Heart sounds associated with different phases of the cardiac cycle are registered in a phonocardiogram as waves varying in amplitude and frequency. When the heart pushes blood into the aorta, an opposing force simultaneously accelerates the body in the opposite direction. The oscillations produced by these movements are detected by the ballistocardiograph, an instrument for measuring cardiac output, and heart rate can be measured from the resulting waveform. If only heart rate is to be assessed, the standard table model of the ballistocardiograph is unnecessarily complicated and expensive. An inexpensive version, consisting of a phonocardiograph attached to the ankle, is entirely adequate for recording heart rate (Brown and Saucer, 1958).

Counting the number of waves per unit time to get average rates is tedious and time-consuming. Measuring the interval between analogous waves in successive cycles in order to compute instantaneous rate is even more so, and only a few devoted investigators have made the attempt (Sontag and Wallace, 1936). Alternatively, the intervals may be read manually and punched on cards for cardiostachometric plotting, that is, transformation to instantaneous rate at successive beats, by a computer (Welford, Sontag, Phillips, and Phillips, 1967). Less time is spent doing arithmetic, but the original reading is still laborious. By far the most convenient means for determining beat frequencies is an instantaneous rate meter. Usually the EKG is fed directly into a cardiostachometer, which is triggered by the R wave and electronically converts each R-R interval to an instantaneous rate. Recently Urbach and his associates (1965) incorporated a rate meter into a telemetered system.

If instantaneous or average rates in a given situation (e.g., age norms under basal conditions) are the only concern, the fact that the association between beat interval and rate is not linear poses no problems. When short-term changes in rate are to be analyzed, however, a decision must be made as to the more appropriate unit of measure-

ment Resolutions of this dilemma and related issues in the choice of a response measure for studying variations in rate and temporal aspects of a rate curve have been reviewed by Steinschneider (1967)

That simple techniques can yield reliable results when carefully applied is indicated by the similarity of the values reported in many older studies in which heart rate was determined by auscultation or palpation to those obtained instrumentally. In 1906 Viernordt gave 130–160 beats per minute as the normal range for cardiac rate during gestation and an average rate of 180 at birth, with a profound drop (mean of about 45 beats) within the next hour. Subsequent series of fetal EKGs, taken from the surface of the maternal abdomen or directly from intrauterine electrodes and totalling hundreds of cases, show average rates of 130–155 (see review in Bernstein, 1961, Brady and James, 1962, Welford, Sontag, Phillips, and Phillips, 1967). Little attention has been directed toward tracing changes in rate with fetal age, but in one study a decline between the fifth and ninth months (means of 156 and 142, respectively) and a slight increase in the tenth was observed (Sontag and Richards, 1938). On the other hand, the course of heart rate during and immediately after labor recently has been the subject of much detailed research.

The accounts of normal and abnormal labors provided by different investigators (Brady and James, 1962, 1963, Caldeyro-Barcia et al., 1963, 1966, Hon, 1959a, 1959b, 1962, 1963, 1966, Mendez-Bauer et al., 1963, Romney, 1966, Sanders, Lind, and Peltonen, 1961, Vallbona et al., 1963) are remarkably consistent. Continuous cardiota-chometric records show the average heart rate of fetuses who undergo a normal labor and are in good condition at birth, as demonstrated by Apgar scores (Apgar, 1953) of 7 or above, to be somewhat above 140 before the onset of labor and between episodes of slowing and acceleration during labor. Among depressed infants (Apgar scores of 6 or less) born after abnormal labors this "basal" rate is at least 20 beats higher. Aside from minor rapid fluctuations, which are present throughout labor, the heart rate of normal fetuses remains at about the "basal" level

during much of the first stage. Near its end and in the second stage larger (10–25 beat) but brief (about $\frac{1}{2}$ - to $\frac{3}{4}$ -minute) decrements or increments occur, decrements being more common. The second stage is also characterized by more frequent variations in cardiac rate. Beginning at the time of crowning and continuing until the first cry there is a period of marked bradycardia (very slow heart rate) when frequencies may normally be below 100.

Several types of bradycardia, apparently with different causes and diagnostic significance, have been described. As labor advances the incidence of bradycardia of short duration associated with uterine contractions, compression of the cord and head, manipulation of the fetus, and pelvic examinations increases in almost all cases. The profound drop at crowning is a reflex response to compression of the cranium on the maternal perineum. Unless slowing occurs in the absence of such factors or persists longer than 60 seconds beyond the end of a contraction the infant is not likely to be depressed at birth. Normal transient bradycardia is thought to result from vagal stimulation, because the conditions under which it occurs would produce hypoxia and because the response can be blocked by administering atropine (which counteracts vagal action) to either fetus or mother. More extreme and prolonged slowing, especially if it is present in early as well as late labor, is indicative of fetal distress. The perinatal mortality rate is tripled among infants in whom bradycardia continued for over half an hour. As might be expected, severe bradycardia is most often noted in circumstances that augment the normal, transient disturbance of the uteroplacental circulation, for example, maternal hypoxia and hypertension, toxemic pregnancies, intense uterine contractions, and looping of the cord about the fetal neck.

The same factors that appear to precipitate normal "dips" in heart rate may sometimes produce temporary tachycardia (excessively rapid heart rate). In other instances no probable cause of the acceleration can be discovered. Persistent tachycardia has been observed in connection with acidosis and respiratory depression and is prognostic of poor condition at birth. However, the like-

likelihood of death, even among fetuses with tachycardia of several hours duration, is less than in those suffering much shorter periods of bradycardia. Tachycardia has been interpreted as a defensive response stemming from an increase in the activity of the sympathetic nervous system initiated by acidosis and hypoxia. With a faster heart rate, cardiac output rises, improving the metabolic interchange between fetus and mother. A rise in sympathetic tone also promotes vasoconstriction in nonessential tissues, so blood is diverted to the heart, brain, and placenta. Between uterine contractions or with the cessation of other sorts of interference with the uteroplacental circulation a drop in heart rate helps to conserve the energy resources (stored glycogen) of the heart. It is of interest here that when the mother is given injections of glucose, bradycardia during crowning is eliminated.

Although the overall postnatal trend in cardiac frequency is downward (see Tables 5 and 6), there is a reversal during the early days. In addition, vigorous and distressed infants continue to differ in their patterns of change in heart rate following delivery. After the first cry, beat frequency normally rises abruptly (in about 2 minutes) from the low level induced by crowning to a peak of 170–180. When the cord of healthy neonates is clamped before respiration is initiated, bradycardia intervenes briefly. Otherwise, the time of clamping has no particular effect on heart rate. Whether clamping is early or late, the heart rate next stabilizes temporarily at about 165–170. Between 15 and 60 minutes later the rate has dropped by 40 to 50 beats per minute. Asphyxiated babies who do not breathe promptly (Apgar scores are, of course, low) have continuing and increasing bradycardia until the lungs expand. Thereafter, their heart rates are generally higher than normal, with a mean over 180.

Normally heart rate declines further but more gradually during the first day and then begins to rise slowly (see data from Benedict and Talbot, 1915, in Table 5). Often the decrease begins while the baby is very active, but it is not interrupted when sleep ensues. A deceleration during activity is in direct contrast to the situation at all later ages. As the means and ranges obtained by Eichorn (1951) and by Keating and Edwards (1888)

illustrate (see Table 5), even a quiet waking state is characterized by higher rates than is sleep. In the former study rates were read from EKGs, whereas in the latter palpation was used. Again, the agreement in values is notable. The data of Lipton et al. (1965) included in the table show the reduction in heart rate when very young infants are swaddled. While swaddled the subjects spent more time sleeping and almost never cried.

Exactly how long the accelerative phase of the rate curve lasts cannot be specified because the day-to-day change in rate has not been traced beyond the first week. Judging from the means found by Eichorn (1951) in cross-sectional groups and by McCammon (1961) in a longitudinal study, deceleration begins some time between 3 weeks and 2 months. Lipton, Steinschneider, and Richmond (1966) tested 14 infants at ages of 2 to 5 days and again at 2½ and 5 months and report significantly higher heart rates both before and after stimulation during the first week. Variability in rate was also significantly greater then. The lability of beat frequency in the young has often been remarked and can be seen in the ranges listed in Table 5. Irregularity of fetal heart rate has been regarded as evidence of vagal tone and the integrity of the autonomic system (Cameron, 1967). Sinus arrhythmia—acceleration of heart rate toward the end of inspiration and slowing toward the end of expiration—is so regular a phenomenon in infants, even the newborn, and children (Keith, Rowe, and Vlad, 1967; Lipton, Steinschneider, and Richmond, 1965; Urbach et al., 1965; Vallbona et al., 1963) that its absence is suggestive of abnormality in cardiac or autonomic function.

Once the long-term decline in heart rate begins it continues without further interruption except for a possible leveling-off or even slight reversal during the time the adolescent growth spurt is at its peak (see Table 6). As is true of most functional measures, the rate of change is steepest during infancy. The norms selected for Table 6 also show the influence of sex and conditions of measurement on the frequencies observed. Of particular interest is the contrast between the means reported by Iliff and Lee (1952) and by McCammon (1961). These data are from the same longitudinal sample examined in

different situations McCammon's come from the EKGs described in an earlier section. The subjects were lying quietly but were neither sleeping nor in a basal state. For their study Iliff and Lee used pulse rates taken early in the morning immediately after tests of basal metabolism and while the children were fasting, quiet, and relaxed. Metabolic tests on infants were made after feeding at various times of day. They slept during the test, and pulse rates were determined as soon as

they awoke. Pulse was counted for at least 30 seconds during palpation of the wrist in children and auscultation (with a stethoscope placed over the heart) or sometimes palpation of the ankle in infants. The lowest rate under these conditions was recorded.

Among the developmental changes that may underlie the overall decline in heart rate are decreasing metabolic rate and body temperature and increasing respiratory efficiency, vagal control, blood pressure, and

muscularity and volume of the heart. The basic function of the heart is to keep the tissues supplied with oxygen and nutrients and sufficiently free of wastes. As growth rate declines, so also does metabolic rate, hence relatively less blood flow is required. The major determinants of blood flow are resistance to flow (vasomotor tone), arterial pressure, and cardiac output, which is the product of stroke volume and heart rate. Under normal conditions, blood pressure and heart rate are negatively correlated. The role of increased heart volume and strength and vasomotor tone have already been cited as influences in the developmental increase in blood pressure. Heart rate is positively correlated with body temperature and changes approximately 11 beats per minute for each change of 1°F in oral temperature (Tanner, 1951). Body temperature tends to vary directly with metabolic rate.

Smith (1959) attributes the immediate postnatal deceleration in heart rate to alterations in vascular resistance, cardiac output, and other aspects of circulatory dynamics rather than to a reduction in metabolic rate, for the latter may actually be increasing. Another possible factor is body temperature, which drops several degrees within an hour after birth and remains low for several more. The extent and direction of the sex difference in temperature which appears during adolescence (see Table 6) and continues into adulthood is just about sufficient to account for the sex difference in heart rate which develops concurrently (Tanner, 1962).

As Lipton et al. (1965) note, an increase in cardiac rate during the first few weeks or months is contradictory to the change that would be predicted from the inverse associations of heart rate with blood pressure and heart weight and volume. They suggest that biochemical changes and increasing sympathetic tone may be responsible for increments in both heart rate and blood pressure. Physiological anemia (see Hematology) may play a role in the transient rise in heart rate. As blood levels of hemoglobin drop, an increase in cardiac output may be needed to offset the lower oxygen-carrying capacity of the blood. From Smith's view of the causes for the fall in heart rate on the first day, the succeeding temporary rise would simply represent a recovery period during which heart

rate returns to levels approximating those before labor.

RESPIRATION

The drama of the first breath has touched the imaginations of physiologists and pediatricians as well as psychoanalysts and poets. In a few brief moments each newborn must abandon one respiratory system—the placenta and its circulation—and make functional another, which is not only untied but also solid and full of fluid. As one authority on the physiology of the newborn has put it, "The first breath of a newborn baby must give even the most experienced physician a small thrill of excitement. Until that sudden withdrawing of air occurs the baby's life is in doubt, even though the heart is beating. Other problems may be put off for hours, days or weeks, but if the baby is to live, it must begin moving air into and out of its lungs within minutes after emerging from the birth canal" (Smith, 1963, p. 27). He goes on to point out that the newborn is a "physiologically displaced person" thrust "into an entirely new medium with such novel physical properties it is astonishing that the infant is able to deal with it so promptly and effectively."

By comparison, the facts that must be known to understand the respiratory process—the anatomy of the respiratory tract, the mechanics of breathing, the physiology and biochemistry of gas transport, exchange, and utilization, and the chemical and neural control mechanisms—may seem prosaic, if intricate. The primary function of respiration is, of course, to supply the tissues with oxygen so that the energy in food can be released for work and heat and to remove the carbon dioxide produced during this combustion. As one of several interrelated and integrated functions, however, respiration also contributes to the control of body temperature and the maintenance of fluid and acid-base balance.

The metabolic processes through which oxygen passes from the blood into the cells and is utilized and by which carbon dioxide is produced and returned to the blood are called internal respiration, gaseous metabolism, or intermediary metabolism. In the last analysis the rate of combustion deter-

mines the amount of air that must be taken into the lungs in order to reduce the excess carbon dioxide and to replace the oxygen that has been removed from the blood. Nevertheless, this phase of respiration customarily is treated apart from external respiration. Subsumed under the latter term are the processes involved in the exchange of oxygen and carbon dioxide between body and environment, that is, the inspiration and expiration of air and the passage of oxygen from the alveoli (terminal air sacs of the lungs).

The circulation supplies the connecting link between external and internal respiration, and the circulatory and respiratory systems are closely integrated. If either is impaired, compensatory adjustments occur in the other. Indeed, the heart may quite properly be considered one of the most important organs of respiration. It and the gas transport mechanism of the blood are limiting factors in the efficiency of respiration, for the ability of the heart to pump blood and the oxygen-carrying capacity of the blood set the rate at which oxygen can be delivered to the cells.

Breathing is the mechanical aspect of the respiratory process. The amount of gas interchange with the atmosphere is determined by the mechanics of respiration, and these in turn depend upon the structural characteristics of the chest and respiratory tract (nasal passages, larynx, trachea, bronchi, and lungs), especially the lungs. Because the development of respiratory function is almost impossible to interpret without some knowledge of the essential apparatus, the more significant features of anatomical development will be reviewed first.

Anatomical Development

Almost coincidentally with the initiation of circulation to the fetal "lung," the placenta, in the fourth week, the bud of the primitive endodermal tube that constitutes the primordium of the lung appears. A day or two later two primary branches, the major bronchi, can be distinguished. Next, the right bronchus, which is larger, produces two side buds and the left only one. This unequal division presages the final plan of the lungs—three lobes on the right and two on the left. By successive generations of branchings these three new buds and the original two each gives

rise to the bronchial tree of one of the five lobes of the mature lung. Cartilage begins to be deposited in the bronchi and larger bronchial tubes at approximately the tenth week, and by the twenty-fourth about as much has been laid down as is present at full term.

Once the bronchial trees are well established, the many lobules that comprise each lobe of the adult lung start to develop. From each of the many terminal bronchioles a number of irregular passageways, the alveolar ducts, are extended. Eventually every duct acquires bushy sacs of alveoli. Several alveolar sacs converge on a common chamber, the atrium, and the atria lead into the alveolar duct.

Very shortly after definitive alveoli begin to be elaborated, the cuboidal or columnar cells of their epithelial lining start to become flattened or platelike, and a network of capillaries proliferates close to the expanding airways. Within another four weeks there are two distinct classes of epithelial cells, one of which contains a substance called surfactant or its precursor. Whether these cells secrete or simply store this material is not known.

Until differentiation of the alveoli and adjacent capillaries, thinning of the alveolar lining, and production of the surfactant have progressed far enough to permit gas exchange commensurate with tissue needs, the fetus cannot survive independently. The alveoli and capillaries provide the surface for the interchange of oxygen and carbon dioxide, and a thin alveolar epithelium makes rapid diffusion of these gases possible. In the mature lung the alveoli remain open and diffusion continues throughout the respiratory cycle. Surfactant is thought to form a surface film on the alveolar lining that helps to keep the air spaces from collapsing each time air is exhaled. The properties and roles of this surface-active material are dealt with more fully in the discussion of the first breath which follows (see pp 50–51).

Exactly when new bronchial tubes and bronchioles cease to be formed and when the alveoli first appear, change the structure and composition of their epithelial lining, and become invested with capillary loops are still matters of dispute. Recent work indicates that most of the bronchial branching takes place by the fourteenth fetal week (Bucher and

Reid, 1961, Cudmore, Emery, and Mithal, 1962)

Although some authorities set the time of appearance of alveoli and capillaries, flattening of the alveolar epithelium, and secretion of surfactant at 26 to 28 weeks (Avery, 1964, Avery and Mead, 1959, Potter, 1953) most studies place these events between the fourth and six months (Barnard and Day, 1937, Bucher and Reid, 1961, Campiche et al., 1963, Gruenwald, 1963, 1966, Loosh and Potter, 1959, Palmer, 1936, Reynolds et al. 1965, Short, 1950). Seven months is the typical "zone of viability," but the fact that some infants born at younger gestational ages survive also supports the contention that these processes basic to postnatal respiratory function have an earlier beginning. This argument is not conclusive, because even at full-term individual differences in the maturation of the lungs are considerably greater than they are at later ages (Cudmore, Emery, and Mithal, 1962, Kikuchi, 1962).

There is general agreement that the number of alveoli and terminal airways and the area of air-tissue interface increase markedly after birth (Barnard and Day, 1937, Bremer,

1935, Bucher and Reid, 1961, Dunnill, 1962, Emery and Mithal, 1960, Engel, 1947, 1962, Foman, 1961, Kikuchi, 1962, Willson, 1928), although estimates of the timing of different types of growth vary. Discrepancies are to be expected, for measurements on the lungs are fraught with technical difficulties, the number of subjects is usually small, tissue must be obtained from autopsies, so some can be assumed to come from cases with respiratory disorders (and, probably, deficient development), and, as just noted, individual differences are considerable in the young.

In Table 7 the widely cited data of Dunnill (1962) are presented together with ratios that illustrate growth rates. The number of alveoli increases at a decelerating pace. By 4 years the child has almost 90% of the alveoli and half of the terminal airways of the adult. At about 8 years the adult levels are reached (the apparent small increment in alveoli thereafter may not be significant). However, the air-tissue interface (amount of alveolar surface area available for gas exchange) more than doubles between then and adulthood, its growth curve approximating that of body mass. Increase in lung size

Table 7 Age Trends in Terminal Respiratory Units

	Age						
	Birth	3 Months	7	13	4 Years	8	Adult
Number of alveoli ^a ($\times 10^6$)	24	77	112	129	257	280	296
Ratio to birth value	— ^c	3.2	4.7	5.4	10.7	11.7	12.3 ^b
Number of airways ^a ($\times 10^6$)	1.5	2.5	3.7	4.5	7.9	14.0	14.0
Ratio to birth value	—	1.7	2.5	3.0	5.3	9.3	9.3 ^b
Air-tissue interface ^a (sq m)	2.8	7.2	8.4	12.2	22.2	32.0	75.0
Ratio to birth value	—	2.6	3.0	4.4	7.9	11.4	26.8 ^b
Body surface area ^c (sq m)							
Ratio to birth value	—	1.4	1.8	2.1	3.2	4.4	9.0 ^b
Air-tissue interface per unit body surface area	13.3	24.8	22.1	27.1	33.1	34.8	39.5
Body weight, ^c ratio to birth value	—	3.6	4.8	6.1	10.1	16.4	18.5

^a Data from Dunnill, 1962. Ratios were calculated from these data.

^b Dunnill estimates these ratios as 10, 10, 21, and 9, respectively.

^c Data for these ratios were taken from pooled age norms from several sources.

after the formation of new units ceases comes, of course, from the growth of existing ones. Other investigators (Engel, 1962, Kikucki, 1962) report that the transition to growth only by expansion of tissue already present occurs at around 3 to 5 years. As long as new units are being differentiated, the possibility of replacing destroyed tissue may remain. Thereafter, regeneration is unlikely.

Engel's (1966) distinction between immature and mature alveolation is of interest in its own right and also helps to explain inconsistencies among anatomists in the age at which alveoli are reported to appear and in the numbers estimated. During late prenatal and early postnatal development the alveoli are small (about one-fourth the adult diameter) and quite flat and undifferentiated. By the end of the first year they are larger, more elevated, and much better differentiated.

Whereas the number of alveoli, their surface area and the total lung volume (about 1/20 to 1/40 of adult value, Engel, 1962, favors the latter estimate) of the newborn are small, the trachea, bronchi, and bronchioles are about one-third, one-half, and one-fourth, respectively, of adult size. Their postnatal growth curve also differs, being more like the "general" curve of growth, with a rapid increase during infancy, an adolescent spurt, and slow, steady increments during the interim. About 30% of the neonate's lung volume is made up of interstitial tissue, in contrast to 10-15% in the adult. Thus the anatomical "dead space" of the neonate's lungs (area not used in gas exchange) is proportionately greater. Helping to offset the resultant reduction in respiratory capacity is the fact that the surface area for gas interchange is greater per unit tissue while the alveoli are small than it is after they increase in size and change in shape.

The large width of the upper parts of the respiratory tract, their absolutely short length, and the deficiency of mucous glands in their linings render the infant more susceptible to infections. At the same time, the smaller absolute size of the passages means that they are more easily obstructed by foreign objects, inflamed tissue, or collapse of the supporting walls. For a number of reasons the lung of the young infant is less resistant to atelectasis (collapse) than is that of the adult. The bronchiolar muscle is thin, offering less sup-

port, there is less collateral ventilation among the terminal air spaces, and the alveoli are smaller in diameter and have a greater curvature. In premature infants and some full-term ones suffering from respiratory distress, the likelihood of atelectasis is enhanced by a deficiency in the amount or composition of surfactant. Because secretion of this substance is now believed to begin quite early in gestation, a deficiency is attributed to some factor, such as an inadequate pulmonary blood supply, that reduces the amount of surfactant or changes its nature.

Among the structural determinants of the resistance of the airways to the passage of air are the length of the tubes, the number in parallel, and their width. The last is the most important, resistance varying inversely with the fourth power of the radius of the tubes. Because the tracheobronchial tree is wide, the amount of pressure needed for the first inflation of the lungs and the degree of resistance to subsequent inflations in the infant are quite great.

The physical growth of the lungs and the temporary expansion of them with each inspiration are limited by the size of the chest. So small is the chest of the fetus that the lungs, although small in proportion to an adult's, are squeezed between the ribs and bear the marks of them. Early postnatal growth of both the chest and lungs are rapid but proportionate, so the depth of respiration continues to be restricted. Later the rate of growth in thoracic diameter begins to outstrip the rate of increase in lung volume.

Additional handicaps to deep respiration are the poor development of the thoracic muscles, the position of the ribs, and the large size of the heart, liver, and stomach. Like all of the infant's muscles, those of inspiration are weak. The tissue of infants has a high proportion of water and a low proportion of nitrogen, an essential component of protein for muscle. Even if the muscles were stronger, little or no elevation of the rib cage is possible because the ribs are still cartilaginous and positioned horizontally. Little change in position occurs during the first year. Throughout the second and third the descent is fairly rapid. By age 7 the angle of descent has become quite similar to that of the adult. The large heart occupies a disproportionate amount of the small thorax,

and the large size of the abdominal organs such as the liver and stomach prevents adequate contraction of the diaphragm.

How this combination of anatomical limitations influences the character of respiration can be seen when one considers the two ways in which inspiration may take place in the adult. The diaphragm can contract, pushing out the abdomen and increasing the linear dimension of the thorax. Alternatively, the ribs can be raised, increasing the cross-sectional area of the chest. Actually, both sorts of expansion occur to some degree in both costal and diaphragmatic or abdominal breathing, but the sequence is different. In costal breathing, the upper ribs move first, followed by bulging of the abdomen. In diaphragmatic breathing the abdomen is extended first, followed by some movement of the thorax. Either type of inspiration is sufficient to fulfill the respiratory needs of a normal person even during mild exercise. Both usually occur in older children and adults.

At all ages diaphragmatic movements provide a greater amount of the total volume of air inspired under ordinary conditions. Among infants, breathing is primarily abdominal, despite the handicaps already mentioned. Costal respiration begins to play a larger role sometime between the fifth and seventh years.

The fluid filling the fetal lungs has been the source of two research questions: (1) Where does it come from?, and (2) How is it removed? For many years it was believed that this liquid was amniotic fluid, inspired during fetal respiratory movements. These movements were another issue of controversy, for some viewed them as "practice" for postnatal existence. Evidence for such movements, and particularly for the aspiration of amniotic fluid as the source of lung fluid, is tenuous (see reviews in Smith, 1959, Adams, 1966, Avery, 1964, James, 1966, James and Adamsons, 1964). Today respiratory movements are thought to occur during the latter part of gestation only under abnormal conditions, for example, when there is some interference with placental gas exchange. Although occasional respiratory-like movements may be normal earlier in gestation, they would be very unlikely to be effective in moving anything into the rather solid lungs. The hypotheses now favored are that lung fluid is either

actively secreted by the lungs or is an ultrafiltrate of blood plasma from the pulmonary capillaries. Because lung fluid and blood differ in some respects, the second alternative requires the additional assumptions of selective reabsorption or secretion of some constituents. Elimination of lung fluid is one of the many events accompanying the onset of breathing.

Onset of Respiration

The establishment and continuation of respiration adequate to postnatal needs involves not only removal of fluid from the lungs but also development of sufficient pressure to overcome the initial strong resistance to inflation, retention of a volume of air between inspirations, even distribution of that volume throughout the lungs, a large increase in pulmonary blood flow over the fetal level (which is brought about by redistribution of the cardiac output), and a nice adjustment of the circulatory and respiratory systems so that the alveoli are perfused by a volume of blood appropriate to the required rate of gas exchange. To an astonishing extent these processes are accomplished by the end of the first respiratory cycle in healthy newborns.

In the course of a vaginal delivery pressure of the pelvic muscles and vaginal walls on the cartilaginous and therefore rather unresistant thorax squeezes a considerable amount of fluid from the lungs. It is expelled through the nose and mouth, and more fluid usually drains out under the force of gravity when the infant is suspended by its feet at delivery. The amount of fluid lost in this way is between one-fourth and one-third of the functional residual capacity (volume of air left in the lungs at the end of a normal expiration) of an infant several days old (Karlberg, 1960). That remaining must be cleared rapidly because by 15 minutes or so after delivery the functional residual capacity is very close to the typical neonatal level. Observations on lambs (Boston, Humphreys, Reynolds, and Stang, 1965) and rabbits (Aherne and Dawkins, 1964) suggest pulmonary lymphatics as one route of elimination. Other possibilities are evaporation and absorption into the blood (Avery, 1964, James and Adamsons, 1964).

Even after the respiratory passageways are open and some air remains in the lungs be-

tween inspirations, force must be generated to bring new air into the lungs. Air flow in and out of the lungs is governed by changes in the intrapulmonary (intra-alveolar) pressure. Between respiratory cycles no air moves because the pressure within the lungs is the same as that of the atmosphere. During inspiration the volume of the lungs is increased, and, because gases expand to fill the volume available to them, the air already in the lungs also expands, intra-alveolar pressure is reduced below atmospheric, and air flows into the lungs. When the inspiratory muscles stop contracting, the elastic fibers of the lungs retract to their original length, intrapulmonary pressure increases above that of the atmosphere, and air is forced out of the lungs. The inspiratory force must also be sufficient to offset the resistance to flow offered by the respiratory tract (discussed earlier) and by the viscosity and turbulence of air.

Additional pressure is required at birth to overcome the viscosity of the lung fluid and the resistance produced by surface tension at the air-liquid interface and force open the undistended lungs. Experimental work with mature fetal lambs (Stang, 1965) shows that a considerable opening pressure must be generated before any air enters the lungs. Beyond that point a small increment in pressure will bring about almost complete inflation. Water is several dozen times as viscous as air and a thousand times as dense. On the other hand, less pressure is required to inflate a lung that contains some fluid than one that is completely collapsed (Avery, Frank, and Gribetz, 1959). This advantageous effect of fluid may result from its effects on the curvature of the airways. Because the surface tension forcing the walls together is inversely proportional to the radius of curvature, spaces distended with fluid are less likely to collapse. Moreover, lungs containing fluid may not be so easily blocked by inspissated material (Avery, 1964).

Of the various sources of resistance to inflation, surface tension at the air-liquid interface is probably the greatest. Almost half the pressure needed for the initial inflation is used to counteract this tension (Nelson, 1966). The fact that surface tension is strongest in small air spaces means not only that the small alveoli are more subject to collapse, but also that in an interconnecting system, such as the air sacs, air from smaller units will tend to

empty into larger ones. Unequal distribution of gases interferes with efficient respiration. Surfactant supplies two properties that alter the surface tension of lung fluid (see review in Mead, 1961). First, lung fluid containing surfactant is able to develop very low tension. Second, surfactant permits surface tension to vary directly with surface area rather than simply inversely with curvature. Thus as the surface area is extended surface tension increases. Conversely, if the alveoli are compressed (a normal occurrence during expiration), surface tension decreases markedly. It is this characteristic that maintains the stability of the air spaces. With pressures in air spaces about equal regardless of their size, air does not move from smaller sacs into larger ones.

Given lungs partially emptied of fluid through pressure on the thorax, the infant delivered vaginally is further aided in inflating his lungs by a reflex expansion of the chest. When the compressed thorax is freed from the confines of the birth canal, an elastic recoil of the chest walls sucks air into the respiratory tract (Karlberg, 1960). The amount of air taken in just about replaces the amount of fluid lost (7 to 42 ml) and can be as much as 20-25% of the total lung capacity. Individual differences in fluid loss and the extent of the recoil may account in part for differences among healthy infants in the effort required for inflation. Some vigorous newborns seem to breathe almost without effort (James, 1966). Measurements made during the first breath (Karlberg, Cheiry, Escardo, and Koch, 1962) show intrathoracic pressures to range from 20 to 70 cm H₂O below atmospheric pressure and the intake of air to vary from 20 to 80 ml. Although the pressures applied and the work required to generate them are considerable, they are no greater than those typical during a good cry after respiration is established.

Why breathing begins is as intriguing a question as how the first breath is accomplished mechanically. The obvious answer—the baby needs to renew his supply of oxygen and rid himself of carbon dioxide—is not sufficient. First and most important, such a statement says nothing about the trigger mechanism(s). Second, newborns who are not asphyxiated, sedated, or otherwise impaired usually breathe almost immediately

and before they are severed from the placental "lung." Speculation about, and investigation of, the way in which respiration is stimulated center around two general classes of stimuli—chemical and sensory.

Once established, spontaneous respiration is controlled by impulses from respiratory centers (inspiratory center and expiratory center) in the medulla oblongata in the lower brain stem. The activity of these centers is regulated primarily by the degree to which they are stimulated by chemoreceptors, receptor cells sensitive to variations in blood chemistry. An increase in the carbon dioxide pressure or hydrogen ion concentration or a decrease in the oxygen pressure of arterial blood activates the respiratory center, but this action is mediated by the chemoreceptors.

In the adult the central chemoreceptors, which probably lie on the ventral surface of the brain stem, are the major chemical regulatory mechanism. They seem to respond chiefly to the hydrogen ion concentration in the cerebrospinal fluid. Hydrogen ions and carbon dioxide pass from the blood into this fluid. The carbon dioxide is hydrated to form carbonic acid (H_2CO_3). Then much of the acid dissociates, increasing the hydrogen ion concentration. In this way the hydrogen ion concentration of the cerebrospinal fluid parallels the partial pressure of carbon dioxide in arterial blood, and hence an increase in carbon dioxide rather than a decrease in oxygen is the chief means by which respiration is adjusted to metabolic need.

The peripheral chemoreceptors, the aortic and carotid bodies (located below the aortic arch and in the bifurcation of each common carotid artery, respectively), normally play a more minor role, although they have an important emergency function. Unlike the central receptors, these bodies are sensitive to a reduction in the partial pressure of oxygen, as well as to increases in the partial pressure of carbon dioxide or in hydrogen ion concentration and have their maximum effect during asphyxia. Whereas the central chemoreceptors are readily depressed by anoxia, excess carbon dioxide, or anesthesia, the peripheral receptors react to oxygen lack. They continue to stimulate the respiratory center despite depression of the central receptors.

As the peripheral receptors are the stimulus for the last gasp, so it is thought they may be the deciding factor in the first. During labor and delivery gas exchange through the placenta is impaired, although to varying degrees depending upon the circumstances. At birth the oxygen tension of arterial blood is below normal and the carbon dioxide pressure and hydrogen ion content above normal even in the healthy products of uneventful labors. Considerable evidence has been amassed to indicate that both the central and peripheral chemoreceptors are well developed by term (see reviews in Brady and Tooley, 1966, Cross, 1961, Nelson, 1966, Purves and Biscoe, 1966). However, if the central receptors are depressed, activity of the peripheral ones may well become the major rather than the minor mediator of chemical stimulation to breathing.

Experimental results and clinical experience support the inference that sensory stimuli are somehow important in the initiation of respiration. The traditional spanking for nonbreathers is but one example. From a watery environment in which it is weightless, warm, and somewhat shielded from light, sound, and vibration, the fetus is propelled by vigorous pressures into a cold, bright, noisy one in which he has weight and is subjected to manipulations. A true experiment in which one possible determinant is systematically varied while others are held constant is difficult to accomplish even for the chemical variables. Especially with the human infant, real control of the sensory variables is impossible.

From work with lower animals (see reviews in James and Adamsons, 1964, and Purves and Biscoe, 1966) it appears that none of the chemical factors (oxygen, carbon dioxide, hydrogen ions) singly will bring about breathing. In combination they are effective. On the other hand, cooling, which is marked at birth (see Temperature), will stimulate regular respiration in the absence of changes in the gas tensions or hydrogen ion concentration of the blood (Dawes, 1965, 1966). Tactile stimuli alone, even when intense and repetitive, will not (Harned, Wolkoff, Pickrell, and MacKinney, 1961).

The failure of independent chemical changes to induce respiration is interpreted to mean either that the chemoreceptors of the

newborn are not responsive to oxygen lack except in the presence of high carbon dioxide pressure and/or hydrogen ion concentration or that the threshold of the respiratory center is so high that stimulation from the peripheral chemoreceptors is not sufficient to induce increased activity. In the adult the responsivity of the respiratory center depends upon the activity of the reticular formation of the hind-brain, and its excitability is a function of the input from sensory receptors. After delivery the level of activity seems to rise, and the flood of sensory impulses may be the reason. Stimulation of baroreceptors by a rise in blood pressure subsequent to cutting of the cord and increased secretion of epinephrine in response to stress may also act as supplementary stimulants to breathing. To date, the evidence suggests that the initiation of respiration is typically multiply-determined. Certainly, if one were designing the ignition for so important a system, prudence would dictate alternative mechanisms.

Development of Pulmonary Function

Standard tests of pulmonary function include lung volume and its components, the distensibility of the lungs and chest, resistance of the airways, respiratory rate, and timed breathing capacities. Also of concern are the distribution of air among alveoli and between alveoli and dead space, the transfer of gases between alveoli and blood in the pulmonary capillaries, and alveolar-arterial differences in oxygen and carbon dioxide tensions. Most of these measures require voluntary effort and conformity to instructions. Among the other problems in testing infants and young children are keeping activity level similar from subject to subject and the apparatus properly adjusted to variations in size and position. Although means have been devised to estimate most aspects of pulmonary function even in newborn infants, of necessity they are often approximations of the conditions prescribed for adults.

When the various tests are used to chart the course of normal development additional difficulties arise. Not only must body size be taken into account, a step that involves a decision as to which measure, say, weight, height, or surface area, is most appropriate, but sometimes also total lung volume or oxygen requirement, that is, metabolic rate

In view of these considerations it is not surprising that authorities sometimes differ in their interpretations of the adequacy of lung function in the young relative to the adult and that comparative statements typically must be made in general rather than exact terms.

The classic instrument for obtaining most measures of lung capacity is the spirometer. In essence this apparatus consists of a container of gas from which the subject breathes via a tube held in his mouth (his nose is occluded) and a recording device for continuous registration of changes in the volume of gas in the container. During the first few weeks of life infants do not normally breathe through their mouths, and children less than about 5 years old cannot be depended upon to retain a tube in their mouths. Therefore a nasal or facial mask is coupled to the tubing. Lung volumes can also be derived from air-flow measurements made with a pneumotachygraph, which is a mesh screen of known resistance to air flow through which the subject breathes. It is attached to a mask, but no tubing is required.

One major disadvantage of masks and tubing is the increase in the dead space through which air must be moved. What would for an adult be a relatively small amount of instrumental dead space may be equal to or greater than the anatomic dead space in infants and cause alterations in the rate and pattern of breathing. Probably the most successful attempt to design a valved nasal mask with little dead space and resistance to air flow is that recently reported by Silverman, Sinclair, and Buck (1966).

The study of pulmonary function need not be entirely a saga of "through childhood with tube and mask." Alternative techniques for measuring lung capacities in which neither piece of equipment is required are standard and impedance plethysmography and barometry. For standard plethysmography the subject lies in an airtight box with only his head or face exposed. As the air around his body expands and contracts with movements of the thorax, the changes in volume can be recorded with a spirometer connected to the box or the changes in pressure with pressure transducers. A total body plethysmograph—one in which the subject is completely enclosed—is used for barometry and impedance

plethysmography. The barometric method depends upon the fluctuations in pressure produced in the chamber when inspired air is warmed by the lungs, becomes saturated with water vapor, and expands. In impedance plethysmography changes in thoracic gas volume are detected by measuring increases and decreases in the conduction of a small alternating current passed between two electrodes attached to the chest. From simultaneous comparisons of volumes and respiratory rates determined by air-flow meter, barometry and impedance plethysmography, and pneumographic recording with a strain gauge like that used in measuring limb blood flow (see Blood Pressure), Polgar (1965) concluded that barometry is the most satisfactory method for infants.

Not all the subdivisions of total lung capacity (maximum volume of air that can be contained in the lungs without rupture) usually measured in adults have been studied in infants and children. Those most frequently assessed are (1) tidal volume, the amount of air moved into or out of the lungs with each breath during normal, quiet respiration, (2) vital capacity, the largest volume of air that can be expired after a maximal inspiration, and (3) functional residual capacity, the amount of air left at the end of a passive expiration.

Lung volumes vary with height and surface

area and to a lesser yet marked degree with chest dimensions and weight but are largely independent of age *per se* (Demuth, Howatt, and Hill, 1965, see also reviews in Shock, 1966, and Smith, 1959). For this reason, most data have been reported as a function of one or more physical measurements without reference to age. Only vital capacity, which is regarded as one of the most useful indicators of pulmonary function, has been related to age with sufficient frequency and at enough points to produce a relatively systematic picture of age trends and sex differences. Unfortunately, the failure of most investigators to adjust for size before plotting by age reduces the inferences that can be drawn about the effect of maturational variables other than gross size.

Although infants cannot be asked to perform a maximal inhalation and exhalation, they can easily be provoked into a highly reliable approximation of it—"crying vital capacity." Within 7 minutes after delivery this volume ranges from about 50 to 100% of that measured several days later (Sutherland and Ratchiff, 1961). From reviews of the literature Nelson (1966) concludes that the vital capacity (and total lung capacity) of the neonate per unit weight is considerably less than that of the adult, whereas Smith (1959) considers vital capacity per unit sur-

Fig 4 Development of vital capacity (a) Males (b) Females

face area to be small, but per unit weight to be roughly equivalent to the adult's. Nelson (1966) also suggests that the vital and total lung capacities of the infant are low because the chest is too flimsy to provide the mechanical leverage needed for full inspiration.

As can be seen in Fig. 4 the curves of increase in vital capacity are similar to the "general" growth curve and show a progressive sex difference. The apparent variations from study to study in absolute values are not statistically significant, but they probably stem from differences in methodologies and subject size. When surface area is taken into account, vital capacity changes little between 10 and 18 years in girls yet increases gradually in boys (Moore, 1951; Shock, 1942). The fact that the increment in boys during adolescence is greater than would be predicted from total body size has been interpreted to mean that lung growth in this period is proportionately greater in males than females (Morse, Schultz, and Cassels, 1952; Tanner, 1962).

Evaluation of the functional residual capacity of the neonate has been of particular concern. This volume must be sufficient to prevent collapse of the lungs. Otherwise almost as much force would be required for each inspiration as for the first breath. Further, this air acts as a buffer during inspiration so that gas tensions in the alveoli are kept relatively stable. All investigators agree (see reviews in James and Adamsons, 1964, and Nelson, 1966) that the functional residual capacity characteristic of the neonate at the end of the first week is established during the first few minutes of breathing. The absolute values vary widely, but they too are small relative to the adult's when referred to either weight or surface area. Nor does calculation of the functional residual capacity, vital capacity, or total lung volume in terms of both body size and basal metabolic rate improve the picture (Cook, Cherry, O'Brien, Karlberg, and Smith, 1955).

According to Avery (1965), the functional residual capacity constitutes about the same proportion of the total lung capacity in infant and adult. However, Nelson (1966) concludes that this ratio is high in the newborn and does not decline to adult levels until the differentiation of new alveoli ceases and the rib cage is completely ossified. He attributes

the higher ratio to a smaller retractive force of the lung consequent upon a smaller number of alveoli and a lower total alveolar surface tension. In support of this hypothesis he cites evidence for a decrease in functional residual capacity per unit body weight during early infancy. Over a wider age range (4 to 18 years), however, the association with weight is positive rather than negative (DeMuth, Howatt, and Hill, 1965).

Neonatal tidal volume is only slightly lower than the adult's on the basis of weight, but it is especially low when referred to surface area (Nelson, 1966; Smith, 1959). The ratio of tidal volume to functional residual capacity is identical in infant and adult, indicating that the alveolar gas tensions of the infant remain as stable from inspiration to expiration. If this were not so, the protection against atelectasis offered by the functional residual capacity would be impaired.

About one-third to one-half of the small tidal volume of the neonate is distributed in the dead space (see reviews in Avery, 1964, 1965, and Nelson, 1966). A figure of 30% is average for adults, so infants with a comparable value are not wasting any larger fraction of their total ventilatory volume. The distribution of air among the alveoli is also equally good in neonate, child, and adult (Strang and McGrath, 1962; Orzalesi, Hart, and Cook, 1965). However, the amount of air required to ventilate the alveoli is dictated by metabolic demand and is proportional to surface area. Therefore the infant must over-ventilate in relation to his body weight, and the ratio of alveolar ventilation to dead space is very high. The latter ratio, together with the product of pulmonary compliance and resistance (see immediately below), are the primary determinants of respiratory rate. Singly and in combination these factors require a progressive increase in respiratory frequency as body size decreases.

Compliance, a measure of the distensibility of the lungs and thorax, is defined as the change in lung volume per unit change in pressure applied to the airways. Despite the many problems surrounding the determination and interpretation of lung compliance in infants (Avery, 1964; Polgar, 1967), the average values arrived at by many different investigators (see summaries in Nelson, 1966, and Polgar, 1967) are remarkably similar. At

delivery lung compliance is comparatively poor. It improves rapidly between 3 and 8 hours later, probably because most of the fluid has been removed from the lungs. Relative to body weight, tidal volume, or functional residual capacity, lung compliance at tidal volumes is equivalent to adult ratios. Across a wider range of lung volumes the neonate is not in as good a position. However, compliance increases with age. The source of the apparent limitation in the young may not be a lesser elasticity of the lung but rather an artifact of having a lung with a larger amount of functional tissue per unit of potential air space.

In contrast to the lung, the thorax of the newborn is extremely compliant and becomes less so with age. The balance between the elastic recoil of the lung, which tends to produce collapse, and that of the chest, which makes for expansion, governs the resting volume at the end of expiration. Within the lung, as we have seen, collapse is counteracted by surfactant. Although the net balance of factors apparently leaves the lungs at the end of expiration rather near to the collapse volume, the normal full-term infant shows no real functional handicap. However, this set of conditions is one more reason that the premature infant, whose status is more marginal in all phases of respiratory function, is particularly susceptible to respiratory distress. After the growth of the thorax begins to outpace that of the lung, the balance of distending and compressing forces swings in the opposite direction, and the negative intrapleural pressure characteristic of the adult thorax at rest develops.

As would be anticipated from the anatomic data cited earlier, the absolute resistance of the airways to air flow is high in the newborn (Nelson, 1966; Polgar, 1967). Relative to the adult a much larger proportion of the resistance is attributable to lung tissue and a lesser proportion to the nasal passages (Polgar, 1967). When resistance is calculated in terms of the average air flow through the airways (ventilation per minute) or per unit of lung tissue, however, the infant is found not to be at a disadvantage. Indeed, as pulmonary resistance declines with the loss of fluid from the lungs, the infant comes to be in a more favorable position with respect to resistive forces.

The volume of air brought into the lung in a given interval of time is the product of the tidal volume times the respiratory rate. When inspiration begins, gas in the dead space is drawn back into the alveoli first, and the fresh air from the atmosphere follows. Thus the alveolar ventilation per unit time is the tidal volume minus the volume in the dead space multiplied by respiratory frequency. In rapid, shallow breathing energy is wasted in frequent ventilation of the dead space. On the other hand, the energy cost of a large increment in tidal volume is high because of the effort required to stretch the lungs. Some increase in both the depth and rate of respiration is the most efficient way for the adult to cope with an increased demand for gas exchange. If an impediment to air flow or some other pathological condition reduces tidal volume or alveolar ventilation, then breathing must be more frequent. For this reason respiratory rate, a seemingly gross measure, has diagnostic utility.

Although even the newborn infant can increase his tidal volume, the structural and mechanical characteristics of his respiratory apparatus make rapid, shallow respiration more economical in terms of energy cost (Polgar, 1967). The individual factors limiting the depth of respiration in the young have been mentioned at various points in the preceding discussion. In brief, these are weak inspiratory muscles, lack of firm ribs positioned at a descending angle, large size of the organs in the thorax and abdomen relative to the space to accommodate them, rather stiff lungs, and considerable absolute resistance to air flow. Yet the demand for gas exchange in the young is high per unit of lung tissue, air-tissue interface, or body size. To compensate for the low tidal volume in the face of this need, respiration must be more rapid. Because the infant also typically meets any increased need for gas exchange or reduction in alveolar ventilation by raising his respiratory rate, this measure is useful not only clinically but also for the psychophysiological studies.

Unfortunately, acquiring accurate records of respiratory rate, especially in young infants, is not easy. Rates counted by observers are likely to be low because respiratory movements are not always detectable, or cannot be distinguished from other movements and

because the observer tires or is distracted. The traditional pneumograph, a flexible, accordionlike rubber tube, also may fail to detect shallow breaths. On the other hand, the weight or tactual stimulation of this or other equipment may alter the rate or pattern of respiration. In any event, erratic breathing such as occurs with sighing, crying, or aperiodic breathing (see review in Smith, 1959), for whatever cause, interferes with both observational and instrumental recording and necessitates making repeated counts over a stated interval.

With increasing age, respiration becomes deeper, gas exchange more efficient (see below), and the oxygen requirement per unit size decreases (see Metabolism), so respiratory rate declines. Illustrative data are presented in Table 8. Those of Dietel (reproduced in Peiper, 1963, p. 311) were secured by counting the moist spots on a sheet of cellulose loosely suspended in front of the infant's nose while he slept after feeding. Eichorn's (1951) subjects were also tested after feeding. Records were made not only during sleep but also during repetitive visual

and auditory stimulation and while the infant was awake but unstimulated. Rates during either visual or auditory stimulation (not shown) were intermediate between the sleeping and unstimulated waking rates. An infant's rubber pneumograph was fastened around the subject's abdomen, and the movements were recorded on a photopolygraph. Iliff and Lee (1952) made counts from visual observations of at least 30 seconds. Infants were asleep and older children rested quietly in a basal metabolism chamber. As described earlier (see Heart Rate), the infants had been fed, but the older children were fasting. The data of Shock and Soley (1939) are also from a longitudinal study. Respiratory rates were counted from the spiograms taken during three determinations of basal metabolism on each of two successive days. Two one-minute counts were made for each gas-sampling period.

Although rates obtained by different investigators on older children agree quite well, the variation among and within studies of infants is even greater than is reflected in Table 8. Deming and Hanner (1936) studied

Table 8 Age Trends in Respiratory Rate

18 infants for the first 11 days of life, using half-minute counts obtained in a plethysmograph. Mean resting rates ranged from 40 to 57 and showed no trend during this period. With more carefully controlled conditions and an improved plethysmograph, Cross (1949) found an average rate of 28.6 (range = 14-51) in 36 infants aged a few hours to 13 days. In another study the mean rate declined from about 53 in the first hour after birth to 43-44 by 12 hours and remained at that level during the rest of the first day (Malan, 1966). Rates were counted by observation when the babies were neither crying nor eating. Like heart rate, respiratory rate in most of the 2- to 5-day-old infants studied by Lipton, Steinschneider, and Richmond (1960) was lower ($M = 54.7$) when they were swaddled than when free ($M = 56.6$). Their measurements were made with a nasal thermistor.

All in all, the guess may be hazarded that the respiratory rate during the first week taken with a reasonably sensitive instrument under an age-appropriate approximation of "basal" conditions is somewhere around 50/minute and declines to a third or less of that figure by the end of adolescence.

After air has reached the alveoli, oxygen must diffuse through the alveolar wall, the interstitial space, the capillary lining, and the red cell membrane and combine with hemoglobin for transport to the cells. Carbon dioxide, which is more readily diffusible, takes an inverse course, except that it exists in the blood in several combined forms instead of attaching to hemoglobin. According to Nelson (1966), the ability of the newborn infant to transfer gases is less than that of the adult because "both the effective pulmonary capillary blood volume and membrane diffusing capacity are relatively low." The former deficiency arises because, although the distribution of air among alveoli is even, not all alveoli are equally well perfused with capillary blood (Ledbetter, Homma, and Farhi, 1967). As new generations of alveoli are formed and then walls become thinner, membrane diffusing capacity increases (Nelson, 1966). Between 4 and 18 years the pattern of increase in diffusing capacity is very like that in lung volume, height, weight, and surface area (DeMuth, Howatt, and Hill, 1965). Gas exchange becomes more efficient during adolescence, the percentage of oxygen in ex-

pired air decreasing and the percentage of carbon dioxide increasing between 12 and 16 years (Shock and Soley, 1939). Greater changes are observed in boys, but by 16 neither sex has achieved the levels characteristic of 20-year-olds.

Until fairly recently the fetus was generally believed to exist in a state of relative oxygen deprivation, hypercapnia (excess carbon dioxide in the blood), and acidosis. These inferences were drawn primarily from measurements made at delivery on blood from the umbilical cord or the arteries of the infant. The fact that the blood of many infants who are vigorous at birth has a low oxygen saturation and fairly high carbon dioxide tension and low pH (these two measures are particularly exaggerated in depressed neonates) suggests that this condition is not of long duration (James and Bunard, 1961). Now that fetal capillary blood (Saling, 1964) and the oxygen tension of fetal tissue (Caldeyro-Barcia et al., 1966) have been sampled during labor, it is known that the hypercapnia and acidosis and to a considerable extent the hypoxemia (low oxygenation of blood) arise during labor and delivery and do not accurately represent conditions *in utero* (see reviews in James and Adamsons, 1964; Romney, 1966; Stahlman, 1966; and Towell, 1966). Continuous gas-sampling from fetal animals (Adamsons, James, Towell, and Lucev, 1965; Meschia, Cottei, Breathnach, and Barron, 1965; Misiakhy, Beran, Spradley, and Garwood, 1960) and observations on a few human fetuses during intrauterine exchange transfusion (Fieda and Adamsons, 1964; James and Adamsons, 1964) also show that the normal fetus has well oxygenated tissues and is neither hypercapnic nor acidotic.

Other data from which fetal oxygen deprivation had been deduced have not been refuted but rather reinterpreted in the light of new information and consideration of additional factors. It is true, for example, that the maternal blood exposed to the chorionic villi has a lower oxygen tension than the alveolar air with which the blood in adult pulmonary capillaries equilibrates (Romney, 1966; Sjostedt, Rooth, and Calhira, 1960), that the placenta itself consumes oxygen (Campbell, Dawes, Fishman, Hyman, and James, 1966; Tremblay, Sybulski, and Maughan, 1965), and that oxygen diffuses through the placenta

more slowly than through the adult alveolar membranes (Eastman and Hellman, 1961). Relative to fetal metabolic needs, however, the placenta performs about as well as the adult lung in most aspects of oxygen transfer (James and Adamsons, 1964). The rate of blood flow rather than diffusion is the limiting factor in the degree of exchange of substances across the placenta. Both the fetal cardiac output and rate of placental blood flow are sufficiently high to offset the low oxygen tensions of placental and fetal blood (see reviews in Nesbitt, 1966, Romney, 1966, Stahlman, 1966, and Towell, 1966). Of course, interference with the placental or fetal circulations can reduce the amount of oxygen available to the fetal tissues.

Certain peculiarities of fetal blood (see Erythrocytes), have long been recognized as a protection against oxygen lack. For several reasons the oxygen-carrying capacity of fetal blood is higher than that of adult blood. When enclosed in erythrocytes and in the blood stream, fetal hemoglobin has a greater affinity for oxygen at a given oxygen tension, although when separated from the red cells it does not (Allen, Wyman, and Smith, 1953, Nechtman and Huisman, 1964). Whatever the environmental source of the difference may be, the net result is that fetal blood takes up oxygen at tensions at which the maternal blood in the placenta releases it. The uptake at the placenta is further enhanced by simultaneous release of carbon dioxide (Bohr effect). At the oxygen tensions of fetal tissues and with the acidity there, however, the fetal oxyhemoglobin curve is such that an inverse and equally advantageous phenomenon is observed—oxygen is released more readily. These characteristics of the fetal oxygen dissociation curve, first demonstrated *in vitro* (in a test tube), have now been shown to hold *in vivo* across its entire range (Oh, Aicella, and Lind, 1965). The reader will also recall that as gestation proceeds the number of erythrocytes and then hemoglobin concentration increases, becoming as high as or higher than in the adult.

Within minutes after the establishment of respiration a marked rise in arterial oxygen tension and drop in carbon dioxide tension occurs, and the alveolar oxygen tension and alveolar-arterial difference in carbon dioxide tension are like those of the adult (Nelson,

1966). However, the arterial oxygen tension (and hence the alveolar-arterial difference) does not reach adult levels for several days, even in normal full-term infants (Thibeault, Clutario, and Auld, 1966). Alveolar and arterial carbon dioxide tensions—the latter is considered to be the most reliable index of the adequacy of alveolar ventilation (Avery, 1964)—are somewhat low for several weeks (Stahlman, 1961) or months (Nelson, 1966). Although the acidosis present at delivery increases briefly, the acid-base balance is close to normal within 2 or 3 hours and like that of the mother near term by 1 or 3 days (Assali and Morris, 1964, James and Burnard, 1961, Weisbrot, James, Prince, Holaday, and Apgar, 1958). The latter state is one of compensated alkalosis, that is, the pH of the blood is normal, but the carbon dioxide tension is below 40.

The delay in achieving normal adult oxygen and carbon dioxide tensions is usually attributed to the continuation of shunting, which permits some blood to bypass the lungs, but imperfect adjustment between alveolar ventilation and perfusion of the pulmonary capillaries with blood probably is also a factor (Ledbetter, Homma, and Farhi, 1967). Probably the temporary rise in acidosis is a joint result of the loss of the placenta as a route for excreting hydrogen ions and the inability of the kidneys to handle the increased load (Assali and Morris, 1964). Respiratory adjustment to acidosis, that is, the exhalation of carbon dioxide, is rapid, but the metabolic response via the kidney is slower. A low plasma bicarbonate level is the primary characteristic of the compensated alkalosis that follows, and this, too, reflects the function of renal (kidney) and other ion transport mechanisms. Perhaps the rather slow-acting central chemoreceptors are as sensitive in the neonate as adult, but their homeostatic "set-point" for carbon dioxide is lower, like that of the pregnant female, because of depletion of the bicarbonate buffer system (Nelson, 1966). If the control mechanism were "set" differently, the ventilatory stimulus for exhalation of carbon dioxide would continue until the kidney and other ion transport mechanisms were able to conserve bicarbonate.

Because the blood loses its qualitative and quantitative fetal characteristics somewhat gradually, neonatal blood also has a higher oxygen saturation at a given tension than does adult

blood. On the other hand, this aid to the oxygenation of tissues may in part be counteracted by the retention of another peculiarity of fetal blood—a low level of carbonic anhydrase (Smith, 1959). This enzyme catalyzes the conversion of carbonic acid to carbon dioxide and water, facilitating the transfer of carbon dioxide from tissue to blood and blood to lungs, and, indirectly the uptake of oxygen. However, the significance of the deficiency really is not known. Males have been reported to show a larger increase than females during adolescence in the blood levels of carbonic anhydrase (Lawrence, 1947). There is a rise in the alveolar and arterial carbon dioxide tensions of boys during adolescence (Shock, 1941), and the sex difference is maintained in adulthood (Shock and Hastings, 1935).

Sufficient cooperation and motivation can be secured from children beyond the pre-school age to make timed and other special tests of pulmonary function. A number of investigators have tested maximal breathing capacity, the volume breathed during 15 seconds when the subject respines as deeply and rapidly as possible (Cassels and Moise, 1962, Ferris, Whittenberger, and Gallagher, 1952, Ferris and Smith, 1953, Kennedy, Thursby-Pelham, and Oldham, 1957, Moore, 1951), and flow rates, the rate of air flow adjusted to a standard respiratory rate (Chiang and Han, 1965, DeMuth, Howatt, and Hill, 1965, Heaf and Gillam, 1962, Kennedy et al., 1957, Lyons, Tanner, and Picco, 1960, Muriay and Cook, 1963, Naun, Bennet, Andrew, and MacArthur, 1961, Strang, 1959). In general it can be said that these measures follow the same developmental pattern as vital capacity, increasing steadily with age and size until puberty. Then a steeper increment occurs, particularly in boys, for whom the increases are greater than would be predicted from physical growth alone. Factor analyses by varimax rotation yield an axis that involves vital capacity, functional residual capacity, diffusing capacity, thoracic cage size, and to some degree peak expiratory flow rate (DeMuth et al., 1965). A second axis is highly related to various measures of flow rate.

Age trends after adjustment for size have been examined only for maximum breathing capacity. Allowing for surface area, there is still an increase from 10 to 20 years in both

sexes. Many sex differences observed when measures are related to body size disappear when vital capacity is used as the referent (DeMuth, 1965). Longitudinal studies show the relative standing of individuals on various lung volumes and other measures to be consistent across time (DeMuth et al., 1965).

Neither timed vital capacity nor the flow rate at the point at which half the vital capacity has been expired follow the general growth pattern. The trend for the latter measure is like that for airway conductance, the reciprocal of airway resistance (DeMuth et al., 1965). In contrast to their performance on all other tests, children aged 6 to 14 deliver a higher proportion of their vital capacity in 1 second (timed vital capacity) than do adults (Lyons et al., 1960).

METABOLISM

In its most general sense metabolism (derived from a Greek word meaning alter, change, or turn about) encompasses all the physical and chemical processes by which food is converted into energy, new tissue, and wastes. Thus construed the term includes respiration, digestion, absorption, catabolism (the breakdown of ingested or stored substances into simpler compounds), anabolism (synthesis of more complex compounds from simpler ones), energy transformations, secretion, and excretion. Usually, however, metabolism is defined more specifically as the chemical transformations occurring between absorption (the uptake of nutrients from the digestive tract into the blood) and elimination. External respiration, digestion, and elimination involve physical as well as chemical action.

Metabolic reactions have two aspects that may be, and typically are, studied separately. Biochemists analyze the series of changes which newly absorbed or stored nutrients undergo as they are completely catabolized to wastes (largely carbon dioxide and water) or through which by-products of catabolism are recombined for storage or the repair or creation of cells (anabolism). Individually these intricate sequences are referred to as fat metabolism, protein metabolism, and carbohydrate metabolism. Collectively they are known as intermediary metabolism. As noted earlier, internal respiration is involved, for

all but a few limited metabolic reactions require the presence of oxygen at some point and carbon dioxide is one of the end-products of most. The major "wastes" of intermediary metabolism are important factors in the regulation of fluid and acid-base balances, respiration, and the maintenance of body temperature. However, developmental variations in metabolism are of a quantitative rather than a qualitative nature, hence there is no need to consider intermediary metabolism any further here.

Energy transformations, the other aspect of metabolism, are the source of power for all physiological processes. The form in which energy is expended in a particular process may be chemical, electrical, thermal, or mechanical, but it is originally derived from the chemical energy liberated when food is oxidized. At each step in the breakdown of food a small amount of chemical energy is released. Some of this energy is used immediately to fuel ongoing bodily functions. Any excess is dissipated as heat or stored in the fats, proteins, and carbohydrates or special energy-rich phosphate compounds synthesized by the body. If the intake of food is insufficient to supply the energy needed to perform work and maintain body temperature, stored energy is used.

Because energy can be neither created nor destroyed, only transformed, the energy released from ingested food = work energy + heat energy \pm stored chemical energy (energy balance equation). In principle, the metabolic rate (amount of energy transformed per unit time) can be determined by measuring the terms on either side of this equation, but in practice problems arise. The heat produced when a given weight of a particular food is completely oxidized outside the body is calculated from the increase in temperature of a known volume of water caused by burning the sample in a metal chamber (bomb calorimeter) filled with oxygen and immersed in the water. Although fats and carbohydrates yield as much energy when catabolized as they do in the calorimeter, proteins are incompletely oxidized in the body and do not. Further, determining the quantities and qualities of food eaten is a time-consuming process for both subject and experimenter.

Among the variables that affect energy output and its distribution as work, heat, or

chemical stores are size, age, sex, environmental and body temperatures, activity, secretion of thyroid hormone and epinephrine, and emotional stress (via muscular tension and increased production of epinephrine). To simplify the calculations of metabolic rate, energy production is measured under circumstances designed to eliminate some sources of variation. The subject should be reclining, physically and mentally relaxed, in the post-absorptive or fasting state (i.e., 12 to 14 hours after eating) in an environment of known and constant temperature following 30 to 60 minutes of horizontal rest. These so-called basal conditions, already mentioned in the sections on heart rate and blood pressure, were originally defined for determining metabolic rate because it is so easily altered. Values obtained in this situation are not as low as they are during sleep, when, in addition to being in the postabsorptive state, the subject is more relaxed.

Under fasting conditions energy storage, which is difficult to assess, is eliminated or negative. All energy used for work is eventually converted to heat, thus with the storage component removed, all of the energy output of the body appears as heat. This heat production may be measured directly in a large calorimeter or indirectly by measuring oxygen consumption or the end products of metabolism (carbon dioxide, water, and protein residues such as urea).

Either direct calorimetry or measuring the end products of metabolism is tedious and requires equipment usually available only in specialized laboratories. By contrast, oxygen consumption can be determined fairly easily. Under basal conditions oxygen consumption is set by immediate need, for no oxygen debt is being repaid or incurred, and oxygen is never stored. Therefore the oxygen used in a given period of time directly reflects the amount of energy released.

Techniques for measuring oxygen consumption fall into two classes—open-circuit methods and closed-circuit or spirometric methods. In the former the subject breathes atmospheric air through one tube and exhales into another from which the expired air is collected for analysis of its composition. The spirometer has already been described (see Respiration). Adaptations, similar to those for studying lung volumes, are necessary for in-

infants These include low dead-space masks (Příbylová and Znamenáček, 1966), hoods (Karlberg, 1952, Mestyán, Jaiá, Bata, and Fekete, 1964, Oliver and Karlberg, 1963), and small chambers (Adamsons, Gandy, and James, 1965, Hill and Rahimtulla, 1965, Levison and Swyer, 1964, Stern, Lees, and Leduc, 1965) much like a total body plethysmograph (see Respiration)

Basal metabolic rates obtained in these ways may be expressed simply as oxygen consumption per unit time More frequently oxygen consumption is converted to an estimate of heat production by multiplying by a constant representing the caloric value of oxygen for an ordinary mixed diet For very young infants the current trend is not to convert to Calories (see Table 9) because the assumptions made in doing so may not be fulfilled (James and Adamsons, 1964)

Despite a rather voluminous literature extending over more than a century (see reviews in Benedict and Talbot, 1921, Karlberg, 1952, Sargent, 1961, Shock, 1966, Tanner, 1962), considerable disagreement still exists on appropriate standards for basal metabolic rate, especially for infants and young children

The controversy centers around referents, that is, whether values should be expressed in terms of surface area, weight, or height, muscle mass, etc., and whether age standards should also be used Even when expressed in the same terms, however, the averages obtained by different investigators for a given age or size often vary more than those for adjacent age or size groups within a single study The variations arise primarily from sample differences in body size and adequacy of nutrition and from methodological differences, not only in instrument but in many other variables such as time of day, number and length of tests, time since eating, preliminary rest and adaptation periods, and whether average values or lowest values were reported Absolute differences notwithstanding, the trends observed in different studies are consistent in their major characteristics (see Table 9 and Fig 5) On the basis of weight or surface area, basal metabolic rate begins to increase very soon after birth, reaches a peak sometime in the first year, and remains at this level until the second or third year when a decline begins which continues over the rest of the life span

Table 9 Energy Metabolism in the Perinatal Period

In the latest edition of Smith's *Physiology of the Newborn Infant* (1959) the averages reported by Benedict and Talbot in their classic monograph on the metabolism of the newborn infant (1915) are cited as similar to those obtained by subsequent investigators. Compared to the adult figure of 1.00 Cal/kg/hr, the heat production of the full-term newborn was found to be high, 1.75 Cal/kg/hr (Benedict and Talbot, 1915) to 2.00 (Marsh and Muir, 1925), or an oxygen consumption of 6.2 ml/kg/min (Cross, Tizard and Trythall, 1957) to 6.6 (Benedict and Talbot, 1915). When referred to surface area it was lower—29.16 Cal/sq m/hr for the newborn and 35–50 for the adult (Marsh and Muir, 1925)—as would be expected from the adult-infant contrast in amount of surface area per unit weight (see p. 28).

By an interesting coincidence, the most recent reference in Smith's (1959) review, a 1958 paper by Cross, Tizard, and Trythall, precipitated a series of studies which led to a revision of these estimates of neonatal metabolic rate and to a better understanding of the control of heat production and other aspects temperature regulation (see *Body Temperature*). They reported that the oxygen consumption of newborns decreased when breathing an air mixture so mildly hypoxic as to have no effect on adult man or animals. Research with animals was first undertaken in an attempt to understand this unusual result (see reviews in Adamsons, 1966, and Oliver, 1965). A similar response was observed in newborn animals only in a cool environment. Later this finding was confirmed for the human infant (Oliver and Karlberg, 1963). After further exploration it was concluded that the neutral thermal environment (environment in which the basal metabolic rate is minimal) for the newborn of homeothermic (warm-blooded) species is warmer than for the adult and declines fairly rapidly with age (see review in Mount, 1966). Fust Bruck (1961) and then others (Adamsons et al., 1965; Hill and Rahimtulla, 1965; Oliver and Karlberg, 1963) demonstrated a comparable phenomenon in man. Except for Day's (1943) work with premature infants, the influence of thermal variables had previously been overlooked.

As can be seen in Table 9, these recent

studies place the minimal metabolic rate at birth at about 4.6 to 4.8 ml oxygen/kg/hr, a value that is only about 33% rather than 200% greater than that of the adult. Also of interest is the fact that this level is in the range of the 4–5 ml/kg/hr estimated for the fetus late in gestation (see reviews in Adamsons, 1966; Nesbitt, 1966; Romney, 1966). Like their predecessors, most contemporary investigators find not only an increase in rate during the first day but also further increments in the next few days or weeks, although the timing and extent of the gains are not the same from study to study.

Both in terms of their nature and the ways in which they are presented, the most definitive data on metabolic rate during infancy and early childhood are those from the longitudinal studies at the Child Research Council in Denver, Colorado (Lee and Iliff, 1956; Lewis, Duval, and Iliff, 1943). The population studied is the same as that from which the EKG, heart rate, and respiratory rate data summarized in previous sections were secured. One virtue of these data can be seen in Fig. 5—the overlapping of basal with sleeping, postprandial measures. Except for Karlberg (1952), who examined young infants 4 to 6 hours after a meal and older ones after 12 to 14 hours, most investigators have accepted the conclusion of Benedict and Talbot (1921) that restlessness accompanying hunger causes a greater increase in metabolism than does digestion and have not attempted to approximate basal conditions with children. Lee and Iliff provide systematic data on this point. In the age range at which both types of determinations were made—21 to 36 months—values obtained while the child was awake and fasting were 3 to 9% higher than in the sleeping, postprandial state. Further, measures taken on infants in the latter state were reliable and reproducible. Their variability compared favorably with that for basal determinations in older children and did not differ for tests made between ½ and 3½ hours after feeding.

Another strong point of the papers of Iliff and her associates is that results are referred to several different standards, permitting comparisons among referents within each study as well as with trends and absolute values from other laboratories. Only central line

Fig 5 Age trends in energy metabolism (cal/sq m/hr) (a) Males (b) Females

values plotted from the means for Calories per unit surface area for age are incorporated in Fig 5. However, the tables and graphs of Lee and Iliff (1956) show that on the basis of either Cal/sq m/hr or Cal/cm/hr, metabolic rate rises rapidly to 8 months, the surface area values then remaining constant until 24 months in girls and perhaps as late as 36 months in boys. Calories per unit height continue to increase gradually through age 3. Essentially no change is observed from 1 through 36 months in Cal/kg/hr. Discussion of hypotheses about the factors responsible for these patterns and the increment immediately after birth will be postponed until adolescent changes have been described.

The primary questions for the adolescent period are whether or not there is a reversal in the decline in basal metabolic rate that begins in early childhood, the issue of "physiologic instability," and sex differences. Detailed references bearing on the following conclusions can be found in Sargent (1961), Shock (1966), and Tanner (1962). All possible variations in both mean and individual curves at puberty have been reported, that is, increases, decreases, and no change. Of

course, no change or a slowing in the rate of decline is consistent with the notion of a "prepubertal reaction" first proposed by DuBois (1927). Taking the balance among studies and putting particular emphasis on those in which basal metabolism could be related to indicators of puberty, such as menarche or maximum growth in height (Eichorn, 1955; Shock, 1943), there does appear to be a prepubertal slowing of the deceleration in metabolic rate coincident with the growth spurt (see also Sargent, 1961), followed by a steeper decrement. Despite reports of fluctuations in individual curves during adolescence, the only systematic analysis of intra-individual variability during this period (Eichorn and McKee, 1958) offers no support for the advent of increased instability. Perhaps the fluctuations sometimes observed are artifacts resulting from variations in weight, which affect either weight or surface area standards, or from the fact that random errors are no longer masked by more sizable age changes.

When either surface area or height standards are used, sex differences exist across the entire age span beyond one month accord-

ing to the Colorado data previously cited. The metabolic rate of boys becomes progressively higher than that of girls, all studies showing marked differences in adolescents and adults. Sex differences are not observed during infancy and early childhood if basal metabolic rate is computed in terms of Calories per unit weight. The increase in sex differences in basal metabolic rate at adolescence cannot be explained simply by gross size, that is, surface area, height, or weight. Attempts to account for this fact are, as they should be, related to the more general question of the basic factors determining basal metabolic rate. Because muscle has a higher metabolic rate than fat, lean body mass (which can be estimated in several ways) has been proposed as a better and more "physiologic" referent for basal metabolic rate than weight, height, or surface area. Males have a relatively higher proportion of their weight in muscle than females, whereas the inverse is true for fat. Although differences in muscle mass do account for part of the differences both between the sexes and within sex and size groups, they do not seem to be the complete explanation (Garn and Clark, 1954; Garn, Clark, and Portray, 1953; Tanner, 1962). Hormonal factors are another obvious possibility, particularly as adolescence is approached. There is some evidence that basal metabolic rate is correlated with ketosteroid production in boys but not in girls (Clark and Garn, 1963).

Several variables used to estimate lean body mass (fat-free body weight, body weight minus extracellular fluid, and body weight minus both extracellular fluid and fat) as well as more widely used standards such as surface area and body weight have recently been compared as referents for neonatal metabolic rate (Sinclair, Scopes, and Silverman, 1967). Only weight minus extracellular fluid met the mathematical criteria (Tanner, 1949) for a ratio standard. Many investigators have contrasted the relative merits of height, weight, and surface area as standards with varying results. For example, Lee and Iliff (1956) find the largest number of cases within $\pm 15\%$ of the mean using surface area as the referent. According to Sargent's (1961) analyses, however, surface area does not correct sufficiently for differences in physical size, and weight for height is the best standard.

In an important theoretical paper (Holliday, Potter, Jairah, and Bearg, 1967) evidence is marshalled for a somewhat different basis for the decrease of basal metabolic rate with increasing size both across species and ontogenetically within species. Two factors are needed to explain the lower BMR of large animals, but for the most part, only one is required for the lower rate in adults. In both instances it is proposed that a large proportion of the BMR of an organism derives from the metabolic activity of the primary internal organs—the brain, liver, lungs, heart, and kidney. This approach is a variant on the tissue composition school of thought, in that organs of high metabolic rate rather than types of tissue (muscle, bone, fat) are emphasized.

The decrease in basal heat production per unit weight is postulated to stem from the relatively slower growth of these organs relative to total body weight. Put in slightly different terms, these vital organs must develop rapidly during gestation and early infancy to support life; they constitute a larger proportion of body weight at these times. With increasing age a progressively larger part of growth occurs in other organs and tissues, for example, fat and muscle. To account for species differences a decrease in organ metabolic rate with body size is also assumed. Within a species, however, no decrease during growth in the metabolic activity of the vital organs is posited after early infancy (say the first half year or so in man). Evidence for an increase during this period comes not only from the rise in total basal metabolic rate, but also from studies indicating increased activity of the kidney (Holliday et al., 1967) and brain (Kerpel-Fionius, Varga, and Mestyán, 1961). It should be noted in passing that a low rate of cerebral metabolism has been suggested as one reason that the fetus and newborn infant are more resistant to anoxia than older persons (Kerpel-Fionius et al., 1961).

Dawes lists other changes that would make for an increase in oxygen consumption during early infancy: adaptation to an environment cooler than the intrauterine one, the work required for respiration, increased gastrointestinal activity after feeding begins, improved muscular tonus, and the increased muscular work required to oppose gravity in

a gaseous as contrasted to a fluid medium. Although muscular activity is responsible for only a small proportion of the BMR in either the basal or postprandial state (Holliday et al., 1967), this factor and perhaps others, such as hormonal levels, could account for the residual variance. That is, these variables may be the fine adjustments imposed upon the more major one of organ metabolism.

Of course, a person's food intake must include enough calories to cover the energy cost not only of this basal metabolic rate but also of the factors that are eliminated or minimized in the basal state—activity, growth (storage), specific dynamic action of food (S D A, the energy cost of digestion and assimilation), and loss in excreta. Like the BMR, these variables are influenced by age, size, and sex and other individual characteristics such as endocrine function. The absolute number of calories needed daily for each of these categories, particularly activity, increases from birth through the cessation of growth, then drops. After remaining relatively constant during young adulthood, caloric needs decline further in middle and old age.

In computing the allowance for activity, nutritionists take into account the increased energy demand that activity makes on vital activities, for example, respiration and circulation, as well as the cost of muscular movements. Even for adults, some allowance must be made for growth, because the need for repair and replacement of cells continues. The composition of the diet affects both S D A and the caloric loss in excreta. For example, the S D A of proteins is much higher than that of fats and carbohydrates.

None of the specific nutrients (vitamins, minerals, protein, etc.) that have been shown to be essential in the human diet are age, size, or sex specific in a qualitative sense. Instead, the variations in requirements are quantitative (National Academy of Sciences, 1958). Certain deficiencies are more common in particular age or sex groups either because of relatively higher requirements or the nature of the typical diet. Iron deficiency, probably the most common of nutritional deficiencies, is illustrative of both causes. Infants, children, adolescents, and adolescent and adult females have a relatively greater need for iron than do adult males. Milk, the primary constituent

of the young infant's diet, is a poor source of iron.

BODY TEMPERATURE

The temperatures of different regions of the body and the extent of the range among them varies with environmental and physiological conditions. However, animals that are homeothermic ("warm-blooded") must keep their core temperature—the temperature of internal tissues and the central nervous system—within quite narrow limits if life is to be maintained. "Under normal conditions thermal constancy exceeds that of other variables defining the internal environment" (Adamsons, 1966, p. 599).

Tight controls are assumed to be necessary because the rate of all chemical reactions, especially those catalyzed by enzymes, is much influenced by temperature. Many vital processes are brought about by chemical reactions, but without enzymes most of these reactions would take place so slowly that they would be completely ineffective. For example, almost all the thousands of steps in intermediary metabolism are accelerated by enzymes. The optimal temperature range for the operation of enzymes is very small. Below this range reactions become progressively slower, and above it they occur with increasing rapidity until a point is reached at either extreme at which the enzyme in question is inactivated. Tissues with a high basal metabolic rate, such as the brain, are less tolerant of temperature change than are less active ones, such as the skin. In this connection, the convulsions and delirium accompanying high fever immediately come to mind.

Body temperature reflects the balance between heat production and the heat lost through radiation, convection, conduction, and evaporation. Radiation is the transfer of heat in the form of electromagnetic waves between objects that are not in contact. Because radiation takes place from and to the surface of the body, the variables involved in such loss or gain of heat are the effective radiating area exposed (which can be altered by changes in position and the amount and type of clothing), the average surface temperature of the body, the mean radiant temperature of objects in the environment, and the emissivities of the skin and object surfaces.

For convection—the exchange of heat through the movement of molecules in a fluid or gas—the important factors are the temperatures of the skin and of the air or fluid, the effective convective area of the body, and air flow. Within the body, heat moves from the core to the surface by convection through the blood stream and the upper respiratory tract. In the former case, of course, blood is warmed, and in the latter, air is. Comparatively little heat is lost from the surface of the body by convection unless air is moving. However, convection promotes conduction, the transfer of heat from an object to those it is touching in proportion to the temperature difference between them. Again, human beings usually lose little heat this way, but some is conducted through the tissues, and some is lost in warming ingested fluids and food. If the body is immersed in water, considerable conductive loss occurs.

Even when an organism is neither panting nor sweating, some heat is constantly lost through vaporization of water from the lungs and skin. The magnitude of the evaporative loss depends upon the rate of alveolar ventilation, the amount of sweating, skin temperature, and the humidity and movement of air. Water continuously diffuses through the skin (insensible perspiration) and is evaporated, removing heat from the body surface. At high temperatures sweating is prominent in man and panting in lower animals.

Automatic protection in a cold environment is offered by insulation (fat and hair), circulatory adjustments (cutaneous vasoconstriction and shifts in limb blood flow), and increased heat production. Although human beings have little hair and do not benefit much from its erection in cold, they can add to their insulation with clothing. In all homeotherms stability of the core temperature is accomplished at the expense of the periphery. Constriction of the blood vessels in the skin reduces the amount of heat carried to the surface. As a result, temperature at the periphery is lowered, the gradient between surface and environment decreases, and less heat is lost. Cooling is particularly noticeable in the limbs, which account for a large proportion of surface area. In the adult, for example, the hands and feet make up about 15% of the total surface area, yet the heat lost from

them can be reduced by vasoconstriction to 2% of the total loss.

Below a given temperature (25° C in the nude adult male), vasoconstriction is maximal, so cold must be counteracted by increasing heat production. Metabolic rate can be raised by shivering or through voluntary or semivoluntary movements. Shivering is the more effective mechanism, because no heat is wasted in doing work or by increased exposure of the skin. Nonshivering thermogenesis, brought about by increased secretion of certain hormones, is thought not to be an important source of heat production in the adult. As we shall see, peculiarities of the newborn may make this variable more effective. Whatever the cause of increased heat production, more fuel is required. If the intake is not increased, body stores are used.

When a homeotherm is in a warm environment very little adjustment can be achieved by lowering the metabolic rate, despite the common adult reaction "it's too hot to move or eat." Often infants become restless when too warm and thereby increase their heat production. The major facts, however, are that a minimal metabolic rate is needed to supply energy for vital functions and that above a critical temperature the rate of biochemical reactions, and hence heat production, increases progressively with environmental temperature. Again, circulatory adjustments are the first line of defense. Blood flow to the surface and through the extremities is increased. But in heat, too, there is a maximum temperature beyond which changes in circulation are inadequate (34° C in adult man). Sufficient heat cannot be dissipated because the temperature gradient between the skin and the surroundings is so far reduced or even negative. At this point evaporative loss via sweating must occur. If the organism is working, the temperature at which sweating begins is lower.

A neutral thermal environment is one in which core temperature remains within the normal range while oxygen consumption is minimal. From the preceding description of variables influencing heat loss, it is clear that this set of thermal conditions includes not only air temperature but also such variables as the temperature of objects in the environment, air flow, and relative humidity. The characteristic core temperature of homeo-

therms differs from species to species, with age within a species, and to a slight degree among adults within a species. So also do the level and range of the neutral thermal environment, a fact which came to be recognized in the course of recent research, particularly with the newborn, causing a change in the definition of homeothermy. No longer is maintenance of a constant body temperature over a wide range of environmental conditions the crux of the definition. Rather, the distinguishing characteristic of homeotherms is that in the event of heat loss exceeding heat production, responses occur that lead to the conservation of heat, and, when needed, an increase in metabolic rate.

Reflex reactions directed toward maintaining thermal stability are integrated by two perhaps not completely independent hypothalamic centers, one in the posterior hypothalamus controlling responses to cold and one in the anterior hypothalamus for reactions to heat. Input to these centers comes from central receptors within the anterior hypothalamus and from temperature receptors in the skin. Because the degree of hypothalamic cooling required to activate strong reactions is greater than that typical on exposure to cold, cutaneous receptors are thought to play the major role in stimulating the defense mechanisms against a decline in body temperature. In contrast, central receptors apparently provide the primary stimulus for response to heat. The latency of sweating is long, and sweating seems to be more highly correlated with brain temperature than with skin temperature. Efferent impulses activating reactions to heat and cold are mediated by the sympathetic nervous system. Within the hypothalamic centers catecholamines may serve as synaptic mediators, serotonin for the cold center and norepinephrine for the heat center.

According to the old definition of a homeotherm given earlier, the newborn human infant was considered poikilothermic (cold-blooded). By the new one, he is a homeotherm, albeit a less adequate one than his parents. Contrary to frequent assertions, his difficulties do not arise from immaturity of the neural regulatory mechanisms, for within 15 minutes of birth premature as well as full-term infants respond to cooling by vasoconstriction and a marked increase in heat production

(Adams, Fujiwara, Spears, and Hodgman, 1964; Adamsons, Gandy, and James, 1965; Bruck, 1961; Píbylová and Znamenáček, 1966). There is speculation that the low arterial oxygen tension consequent upon labor and delivery would probably make it impossible for the newborn to increase his heat production immediately (Adamsons et al., 1965; Oliver, 1965).

At least by the age of 2 to 3 hours the metabolic response to cold is as good as that of the adult on the basis of body weight (Adamsons et al., 1965; Bruck, 1961; Hill and Rahmtulla, 1965). The magnitude of this reaction is particularly surprising in view of the fact that human infants ordinarily receive little or no food during the first 1 or 2 days of postnatal existence.

On exposure to heat premature and full-term infants also show a vasomotor response, vasodilation (Adams, Fujiwara, Spears, and Hodgman, 1964; Bruck, 1961; Young and Cottom, 1966), on the first day, although as noted earlier (see Circulation) it may not be as good as it is a few days later. Panting respiration has been noted in the premature (Adams et al., 1964). Unlike previous investigators (see review in Lipton, Stemschneider, and Richmond, 1965), Bruck (1961) produced some sweating in full-term infants on their first day. He did not attempt to test the response of premature infants to high temperatures. Others (Adams et al., 1964; Day, Calhoun, Kamenski, and Ehrlich, 1964) have since reported the sweating response to be poor, especially in the premature infant, but the problem seems to lie more in the glands themselves (Watson and Lowiev, 1967) than in their control.

In dealing with cold, the neonate is also handicapped primarily by physical characteristics, in this case, small size, a large surface area to mass ratio, and poor insulation (Adamsons, 1966; Hill, 1961; Mount, 1966; Oliver, 1965). Insulation, surface area, and the temperature gradient between the skin surface and the surroundings determine the rate of heat loss from the body. The lower limit of thermal conditions at which a homeotherm can maintain his core temperature is set by his maximal metabolic response to cold and his minimal effective thermal conductance. Thermal conductance is the difference between core and skin temperatures and varies

with insulation, the surface area-mass ratio, and vasomotor control. Only with respect to the last factor is the newborn in as favorable a position as the adult.

Because the neonate's layer of subcutaneous fat is thinner, his thermal conductance is greater. Therefore his skin temperature is higher relative to the surroundings and he loses more heat. At resting levels his metabolic rate per unit surface area is lower than the adult's, and his metabolic reaction to cold, although comparable on a weight basis, is poorer relative to surface area. Thus the point at which heat production can no longer match heat loss is reached sooner. These physical factors combine to produce a heat loss about four times greater than that of the adult (Bruck, 1961).

Given such limitations, the neonate would be expected to need a neutral thermal environment higher in temperature and narrower in range than does the adult. Other conditions (e.g., humidity, approximation of environmental temperature to that of radiant surfaces) being equal, the neutral thermal environment for the adult is 26 to 31° C (see review in Oliver, 1965), whereas that of full-term neonates is at least 32-34° C (Bruck, 1961, Oliver and Kailberg, 1963, Scopes, 1966). Conditions in these studies may have reduced losses through radiation (Oliver,

1965). Hill and Rahimtulla (1965) report an even higher critical temperature—36° C—on the first day (below the critical temperature metabolic rate begins to rise). Critical temperature declined to 32° C at 7-9 days, but thermal conductance did not change. Scopes (1966) also found a decrease during the first 2 weeks, the critical temperature reaching 29-30° C at 14 days.

Almost all of the observations thus far cited were made on naked infants, and the generalizations from them must be so qualified. The ancient practice of wrapping the babe in swaddling clothes may hamper modern nursing care and experimental observations, but it materially reduces all possible heat losses. Whether swaddling per se makes any difference in the patterns observed may be questioned on the basis of comparable findings with respect to postnatal trends in rectal temperature from both older studies of swaddled infants (see summary in Smith, 1959) and more recent work with naked ones (see Table 10).

In only one study—one in which the infants were delivered into warm wrappings and placed in a preheated incubator (Přibyllová and Znamenáček, 1966)—has the rather dramatic immediate postnatal drop in internal temperature been completely eliminated. Several variables confounded in this treatment

	Nonincubated	31.0-40.0	36.6-38.1	35.5-37.7

are at least partially disentangled in research conducted by Miller and Oliver and summarized by Oliver (1965). To appreciate the point of their comparisons, a brief digression into the natural history of life in the contemporary delivery room and newborn nursery is in order.

Both theoretical calculations and actual measurements show the core temperature of the fetus at term to be about 0.5°C higher than that of the mother, and the skin temperature to be about 2.5° greater than postnatally (see review in Adamsons, 1966). From his liquid environment of about 37°C the fetus is born wet into a gaseous one that is invariably colder—delivery room temperatures are sometimes as low as 15°C , and at least in Great Britain, rarely over 28°C (Scopes, 1966). Until he dries or is dried, considerable heat will be lost through evaporation as well as by other routes, these losses being increased by the steep gradient between the temperatures of the skin and the surroundings. Current routine subjects him to at least one further wetting—a bath in the newborn nursery—and this may be preceded by one in the delivery room. Under these circumstances the drop in core temperature is so steep and rapid, and the accompanying heat loss so great, that a heat production per unit weight twice as great as the adult's would not offset it (Adamsons, 1966).

To the compound of natural and environmental hazards already described other environmental ones may then be added. Despite warm rooms or incubators, typical nursery arrangements make for a radiant heat loss far in excess of that usual for adults (see review in Oliver, 1965). That the full-term newborn's internal temperature begins to climb within 2-3 hours is certainly a triumph of homeothermy.

The experiment described by Oliver (1965) indicates that bathing and subsequent management do affect the postnatal pattern of change in rectal temperature. A group of infants bathed in both delivery room and nursery and otherwise routinely managed had a mean drop in temperature of 2.5°C . One in which only the nursery bath was omitted showed a decline of about 2° . Both groups took 8 hours to achieve a normal core temperature. On the other hand, infants wrapped

and blanketed and placed in an incubator lost only 1° of temperature and returned to normal within 3 hours.

Oliver (1965) also summarizes evidence for the importance of a controlled thermal environment in reducing neonatal mortality and discusses the applications of recent research to the management of both healthy and "high-risk" infants. Several investigators have examined the effect of body and environmental temperature on hormone, carbohydrate, and water metabolism and acid-base balance (Adamsons, 1966, Fisher, Odie, and Makoski, 1966, Příbylová and Znamenáček, 1966).

In the course of his monumental studies Bruck (1961) made several observations about the mechanisms underlying the newborn infant's responses to cold that were subsequently confirmed and expanded by other investigators. First, he noticed that when infants who had been exposed to subneutral environmental temperatures were placed in a neutral thermal environment, their metabolic rate dropped promptly although their rectal temperatures were still low. This phenomenon suggested that the metabolic response to cold was activated by a lowering of skin rather than core temperature. Second, he noted increases in heat production not only following increased activity but also when the infants appeared to be neither moving nor shivering.

As yet there is no consensus on the influence of internal temperature. A significant association between rectal temperature and oxygen consumption has been observed by some workers and not by others (see reviews in Adamsons, 1966, and Scopes, 1966). On the other hand, the role of skin and environmental temperature, or more particularly the gradient between them, has been verified. Oxygen consumption is most highly correlated with the gradient between surface and environmental temperatures (Adamsons et al., 1965). When the gradient was less than 1.5°C oxygen consumption was minimal. Every degree of increment in the gradient beyond this level produced an increase in oxygen consumption of about 0.6 ml. Lower but significant correlations existed between oxygen consumption and absolute skin or environmental temperature. Simply varying facial temperature by either heating or cooling

the foreheads of infants is enough to stimulate changes in oxygen consumption (Mestyán, Jarai, Bata, and Fekete, 1964)

Not all observers agree that the newborn infant shivers (Adamsons, 1966, Scopes, 1966, Thompson, 1966) However, the existence of nonshivering thermogenesis suggested by observations on human infants (Bruck, 1961, Oliver and Kailberg, 1963) has been verified in lower animals using electromyograms (muscle potentials), denervation, and paralysis of muscles with drugs (see reviews in Oliver, 1966, Thompson, 1964) The idea that norepinephrine mediated this response was also revolutionary, but its thermogenic effect is now supported by work with human infants (Kailberg, Moore, and Oliver, 1965, Stern, Lees, and Leduc, 1965) and experimental tests in animals via injections and blocking agents (Moore and Underwood, 1960a, 1960b, Scopes and Tizard, 1963) Human adults, long known to have a thermo-

genic response to epinephrine, may also have one to norepinephrine, but if so, it is much less than that of the newborn (Budd and Waihaft, 1966, Joy, 1963, Steinberg, Nestel, Buskirk, and Thompson, 1964)

Converging lines of evidence pointed to brown fat as the locale of nonshivering thermogenesis in neonatal animals (Dawkins and Hull, 1963, Heim and Hull, 1966) and probably human beings (Aherne and Hull, 1966, Dawkins and Scopes, 1965, Silverman, Zamelis, Sinclair, and Agate, 1964) A review by Hull (1966) should be consulted for details on the structure and function of brown adipose tissue Suffice it to say here that it is distinctive from white fat, is found in considerable amounts in newborn animals but soon atrophies, has a rich supply of blood and of sympathetic nerves, and responds to cold or infusion of norepinephrine with an increase in oxygen consumption and blood flow In the human infant brown fat is found around

the neck, adrenal, and kidneys, behind the sternum, and between the shoulder blades (Aherne and Hull, 1966) These stores are reduced or depleted in infants dying from cold exposure (Aherne and Hull, 1966)

How long nonshivering thermogenesis continues to be important in heat production and temperature regulation has not been determined, studies on children with congenital heart disease suggest at least the first six post-natal months (Oliver, 1965) The longitudinal data presented in Table 11 indicate that the "set point" for basal body temperature is high during infancy and declines with age Unlike the studies included in Table 10, all of these were conducted before thermocouples were available for insertion in the rectum or thermistors for attachment to the skin However, either rectal or oral temperatures taken with a clinical thermometer under carefully controlled conditions parallel core temperature Core temperature is slightly higher than the rectal temperature If the thermometer is in the mouth for a sufficient length of time and the influence of such factors as mouth-breathing and intake of food or fluid is excluded, oral temperature parallels rectal but is 0.5 to 0.75° F higher

The curvilinear trend in the temperature measures of Bayley and Stolz (1937), which are not basal, is quite similar to that noted in basal measures by Benedict and Talbot (1921) The fact that there is no difference in Iliff and Lee's means at 6 and 18 months hints at a comparable trend Of the variables that Bayley and Stolz (1937) examined—crying, season, time of day, illness, and obesity—only the last showed any evidence of an association with body temperature The correlations between rectal temperature and an index of body build were low but positive and significant Among adolescents, Eichorn and McKee (1953) found a positive association between oral temperature and subcutaneous fat in girls and oral temperature and basal metabolic rate in boys In their data the decline in temperature was reversed at menarche in girls and rose for about two years thereafter before resuming the decline At what would be corresponding chronological ages, Iliff and Lee report simply a cessation of the decline

Despite the diurnal variations noted by many investigators, within-day and day-to-

day variations, notable in young children (Bayley and Stolz, 1937, Ludwig and Stolz, 1931), also decrease with age (Bayley and Stolz, 1937, Eichorn and McKee, 1958) These findings suggest that thermal stability continues to improve well beyond infancy

NEUROPHYSIOLOGY

Perhaps this section should be called "Electroencephalography," for that is, with minor exceptions, the subject matter with which it deals The selective emphasis is dictated not by the relative worth of the various types of data bearing upon the functional development of the nervous system but rather by the nature of the information available and the topical coverage elsewhere in this book If value judgments had to be made, strictly behavioral studies would readily be conceded to have provided a larger amount of more immediately useful data not only for the psychologist and neurologist but also for the neurophysiologist "Higher nervous activity," as the Russian psychologists and physiologists term it, is characterized by flexibility, interaction, and integration, all of which are reflected in adaptive, coordinated, attentive behaviors, and by modifiability, as evidenced in learning and memory These behaviors constitute the theme of most of the other chapters

Many insights into the development of normal and abnormal neural function have also been gained from the study of neuromuscular reflexes, such as the grasp, startle, and various withdrawal responses (Dekaban, 1959, Peiper, 1963) Similarly, some investigations of visceral (e.g., circulatory, glandular and gastrointestinal) activity have as their aim the evaluation of the integrity of the autonomic nervous system (Lipton, Steinschneider, and Richmond, 1965) In large measure such vital homeostatic processes are regulated by this division of the nervous system, and about the only way of assessing its function in the intact human being is to examine the rate of reaction and recovery and the degree of stability of these activities With few exceptions, research on reflexive behavior and autonomic function set in the context of neural maturation has been conducted with young infants and hence is included in Chapter 5 (Infancy by William Kessen) Developmental changes in some of the processes subject to

autonomic control, that is, heart rate, blood pressure, and sweating, have been considered in preceding sections of this chapter from the point of view of the physiology of the effector system. Too often the fact that a deficiency in function may result from the state of the effector system rather than from its innervation is ignored when a visceral response is used to evaluate the reactivity of the autonomic nervous system. A case in point—the relatively poor sweating response of neonates—was noted in the discussion of temperature regulation.

Our understanding of function is also broadened by the contributions of neuroanatomy and neurochemistry. Important aspects of the anatomical development of the nervous system are summarized in Chapter 3 (Physical Growth by J M Tanner). Chemical reactions underlie the action potentials of nerves, and transmission at most synapses is chemically mediated. During the past decade developmental patterns in the composition (lipid, protein, water, etc.), enzymic concentrations, and metabolism of the brain have become foci of research. To date, however, most of the work has been with lower animals, and measures on the living human being are particularly scarce (McIlwain, 1966). Except for the research on the electroretinogram reviewed in the chapter on perception (Chapter 10), the only systematic body of developmental data on the electrical activity of the human nervous system comes from the electroencephalogram.

Basis of the Electroencephalogram

If sufficiently amplified, the variations in potential produced by the electrochemical activity of the brain can be recorded from electrodes on the scalp. This tracing is called an electroencephalogram (EEG). One obtained from the surface of the exposed brain or from electrodes inserted into the cortex is also sometimes referred to as an EEG, but the term electrocorticogram (ECG) distinguishes these recordings from those made at the scalp. Although the tracing from a single pair of electrodes—one on the scalp and one elsewhere on the body (monopolar recording) or two on the scalp (bipolar recording)—technically constitutes an EEG, localization of the region of origin of potentials, comparisons among regions, and economy of time

make a number of simultaneous recordings essential.

For many years the most widely accepted hypothesis about the origin of brain waves was that they resulted from the summation of action potentials generated in cortical cells and passed along their axons in the form of the classic all-or-none spike. This concept was challenged by several pieces of evidence (Biazei, 1961). Microelectrode recordings from individual cortical cells show no particular correspondence with the EEG. Further, the impedance (resistance to current flow) of the cerebral cortex is high, and the direct current flow from the inner layers is not strong enough to be detected at the scalp.

Today the EEG is thought to originate from current flow in the thousands of dendrites in the outer layers of the cortex. The physical characteristics of these layers and the nature of dendritic transmission are such that they should produce a pattern like that of the EEG. However, as has been shown by research with lower animals in which pathways to the cortex were stimulated or interrupted at various points, the surface activity is influenced by impulses from the lower levels of the specific sensory systems and the reticular activating system in the brain stem which are relayed via the nonspecific nuclei in the hypothalamus. For example, if a circular incision is made around a cortical area, synchronized electrical activity is not interrupted as long as the blood supply is not affected. Rhythmicity is decreased when the connections to deeper levels are cut.

Methodology

The EEG is being used with increasing frequency in behavioral studies, for example, studies of learning, sensory acuity and adaptation (habituation), stress, individual differences, and response to therapy. As is the case with all research, both the producers and consumers must be aware of the methodological pitfalls, for the value of any study is limited by the care with which the data were collected, and the results must be interpreted in terms of the methods used. These truisms apply with particular force to the fluctuations in potential differences recorded at the scalp. The very characteristic that makes these fluctuations of interest, namely, that they are readily produced by a variety of chemical,

physiological, and psychological variables, means that the experimental conditions must be very carefully controlled. Further, the potentials are of such small magnitude that they are easily masked by larger voltages arising from internal and external sources, and the basic parameters on which evaluations are based—frequency, amplitude, and time relationships—are subject to distortion by the apparatus used for amplification and recording. Artifacts can also be mistaken for true “brain waves.”

Space does not permit a comprehensive treatment of the many sources of interference and artifacts nor of the techniques for recognizing and coping with them. For greater detail on the electrophysiological characteristics of living tissue, the design and inherent limitations of instruments, and the ways in which distortion and artifacts can be detected and corrected, textbooks on electroencephalography such as those by Hill and Parr (1963) and Kilo and Osselson (1961) and instrument manuals should be thoroughly studied. Ellingson (1967a, 1967b) gives good discussions of methodological issues, particularly in dealing with infants.

In certain respects the standard conditions for obtaining an electroencephalogram are diametrically opposed to those for basal metabolic rate and other measures thus far considered. Neither fasting nor a preceding period of protracted sleep is desirable. Fasting is contraindicated because at a blood sugar level of about 70 mg/100 cc. (fasting levels are 60-70) the brain waves become slower than normal, and their frequency is progressively reduced as the level falls further.

Sleep records are of both research and clinical interest, and natural sleep is preferable to that induced by drugs, particularly if the effects of sensory stimulation are to be studied. Although there are sedatives that do not ordinarily affect the EEG, idiosyncratic drug reactions are legion. Physical and mental relaxation are prerequisites for a normal “basal” record, that is, one taken while the subject is awake but resting. Light “blocks” the primary rhythm of the resting EEG, so the subject is instructed to keep his eyes closed. Infants will sometimes do so spontaneously, and until the age of 3 months or so it makes little difference whether they do or not.

For older children and adults, the International 10-20 System (Jasper, 1958) of electrode placement has been gaining widespread adoption. Nineteen electrodes are applied at well-defined locations on the scalp, and a “reference” electrode is attached to each ear lobe. This is too many electrodes for a small skull even if the subject's and experimenter's patience were adequate to the task of applying them. When electrodes are too close together the interelectrode resistance is increased and the amplitude of the potential differences is decreased. A radiographically based 16-electrode adaptation of the 10-20 system and simpler arrays (topographical location of electrodes on the head) have been used with infants (Hellstrom, Karlsson, and Mussbichler, 1963; Ellingson, 1967b). Aside from maintaining sufficient distances between electrodes, the primary criteria are adequate sampling of different regions of the brain and exact placements, preferably ones that can be described in terms of measured distances. The relative positions of external landmarks and the location of regions of the brain in terms of these are not the same in infants and adults.

The long-continued debate over the relative merits of monopolar and bipolar recording has never been resolved. Ellingson (1967b) makes some constructive suggestions in terms of the age of the subject. Because reference electrodes on the ear are not really “indifferent” but pick up activity from adjacent portions of the temporal lobe whenever the rhythms in this region are strong, as they are, for example, in premature infants, the EEG will be deceptively diffuse. On the other hand, a vertex reference lead is poor for sleep recording, for the same reason. During sleep the most salient activity in premature infants and neonates is in this area, and monopolar recordings will be both more diffuse and more synchronous than the underlying activity actually is.

Distinctive features of the EEG used in the analysis of both spontaneous and induced activity include frequency, amplitude, waveform, a number of aspects of temporal and spatial distribution—rhythmicity, continuity, differentiation among cerebral regions, symmetry or synchrony of homologous areas in the right and left hemispheres of the brain—and responsiveness to stimulation. Berger

(1929) labeled the 10 cycle per second waves predominant over the occipital region in the resting record of adults the "alpha rhythm". On the basis of further empirical observations, subsequent investigators divided the frequency spectrum of the EEG into several "bands" designated by Greek letters. Not all workers accept this convention, and the definitions used by those that do vary somewhat. The groupings currently in general usage are: delta, under 4 cps (cycles per second), theta, 4-7 cps, alpha, 8-13 cps, and beta, over 13 cps. Sometimes the beta band is restricted to frequencies of 14-25 sec and faster ones are classed as gamma (Gibbs, 1944, Walter, 1963). In some studies done before the theta division was made, waves up through this range were classified as delta (Henry, 1944).

Ontogeny of the Waking EEG

From either a rational or pragmatic standpoint, normative data on the EEG may be organized under three rubrics: activity while awake but at rest, sleep patterns, and evoked responses. The waking, resting state serves as the standard or reference condition for the sequence of stages of sleep and as the context for most experimental manipulations, although the effects of sensory stimulation and certain other variables are also often examined during sleep.

Tracings from fetuses *in utero* and premature infants are considered first. The terms waking and sleeping cannot properly be applied to those obtained before 8 fetal months, however, for one of the major characteristics of the EEG before this age is the absence of a sleep-wakefulness cycle.

In most respects the problems of *in utero* electroencephalography and the techniques for coping with them are like those for *in utero* electrocardiography. Achieving an adequate signal-to-noise ratio is more difficult because the EEG potentials are of even smaller magnitude than those generated by the fetal heart. Only electrodes over abdominal areas near to the place where the fetal head can be felt will pick up the EEG, but a number of leads should be attached elsewhere to allow for movements of the head and to control for artifacts. Unless the tracing is reasonably similar to that of the newborn infant and differs from simultaneously recorded tracings at other

abdominal sites, it probably is being produced by contractions of the uterus or abdominal muscles, the fetal or maternal EKG, fetal movements, or some combination of these potential sources.

While recording fetal EKGs at the end of the seventh and eighth months of his wife's first pregnancy, Lindsley (1942) noticed patterns in certain abdominal leads that could reasonably be interpreted as an EEG. He verified his impression by the methods just described and by comparing the tracings with a neonatal EEG from the same infant. In the prenatal record most of the waves had a frequency of 6-7/sec, but brief periods of faster activity were frequent. The postnatal tracing from the precentral (motor) region was almost identical. Some years after Lindsley's findings were published reports of intrauterine EEGs (Bernstine, Borkowski, and Price, 1955), and of direct recordings from abortuses (Okamoto and Kuikae, 1951) and premature infants (Hughes, Davis, and Brennan, 1951) began to appear.¹

Even with the accumulation of additional observations on fetuses *in utero* (Bernstine, 1961, Bernstine and Borkowski, 1956, Gianneli, Pavoni, and Scopetta, 1963, Huhmai and Jarvinen, 1963) and abortuses (Aresin, 1962, Bernstine, 1961, Borkowski and Bernstine, 1955, Schwartz and Aresin, 1964) the circumstances of recording are such that the data are neither plentiful nor very informative. Except for one study in which intracerebral electrodes were used (Bergstrom and Bergstrom, 1963), intrauterine tracings have not been obtained until fairly late in gestation, and no localization is possible. A few fetuses have been examined before they were removed from the amniotic sac (Bergstrom and Bergstrom, 1963, Okamoto and Kuikae,

¹ Abortuses may be the product of either spontaneous or induced deliveries, the criteria for inclusion in this group are a weight of less than 500 grams (which corresponds to a fetal age of about 5½ months) and failure to survive. If a fetus weighs more than 500 grams at birth it is classed as premature whether or not it is viable. Extensive bibliographies and reviews of the methods and results of work with fetuses *in utero*, abortuses, and premature infants can be found in the interpretive summaries of Bernstine (1961), Dreyfus-Brisac (1964, 1966), and Ellingson (1967b),

1951), but no abortus can be assumed to be in a normal physiological state. EEGs from both types of sample may be simply and similarly described as composed of discontinuous, irregular slow waves (0.5–2/sec) of low to moderate amplitude upon which a considerable amount of low voltage faster activity (as high as 40/sec) is superimposed. Thus, in very general features these tracings resemble those from older viable premature infants (see below). The significance of studies on abortuses lies mainly in the demonstration that the human cortex is generating electrical potentials by at least the second fetal month (Bernstine, 1961, Schwartze and Aresin, 1964).

In contrast, a detailed account of the evolution of the EEG from the fifth month through term has been derived from the much larger literature on premature infants (Bernstine, 1961, Dreyfus-Brisac and Blanc, 1956, Dreyfus-Brisac, 1962, 1964, 1966, Ellingson, 1964a, 1964b, 1967b, Mai and Schaper, 1953, Palesi and Vannucchi, 1958, 1959, Pohkanina, 1962). With minor exceptions (Dreyfus-Brisac, 1966, Dreyfus-Brisac, Flescher, and Plassait, 1962), the EEGs of premature infants surviving to a given age are like those of infants born at that age, so earlier tracings from the more premature probably reflect maturation *in utero* quite accurately. This inference is not applicable to records made on fetuses delivered in the fifth month nor to most born during the sixth, for they are likely to be anoxic, and few infants born under 7 months of age live very long. Also, individual variations in rate of development are considerable (Ellingson, 1967b). Some infants of less than average maturity may in the course of a week become relatively advanced while others remain generally retarded or advanced. Further complications are introduced by the fact that there are a number of ways of estimating fetal age (e.g., from the first or last day of the last menstrual period or from 2 weeks after the first day) and a term for each (e.g., gestational age or menstrual age), but the usage of these terms by different authors is not consistent. In the present discussion ages are based on a 9-month schema, because the average gestation period is 270 days.

Granting the reservations about viability,

individual differences, and specificity of ages, a number of generalizations about the prenatal development of the EEG can be drawn from the work with premature infants. The features common to the period from 5 through 7 months are discontinuity, occasional paroxysmal outbursts (sudden appearance of a series of potentials differing in frequency and/or amplitude from the prevailing activity), failure to react to stimulation, and absence of interhemispheric (bilateral) synchrony and of a sleep-waking cycle (Dreyfus-Brisac, 1962, 1964, 1966). On the other hand, many rapid changes can also be discerned during this time (Dreyfus-Brisac, 1962, 1964, 1966, Ellingson, 1964a, 1967b). In the fifth-month record, polymorphic rhythms appear in bursts, chiefly over the occipital areas, between periods of electrical silence lasting from a few seconds to a few minutes. Superimposed faster activity is seen in the occipital, occipitotemporal, and central regions. The tracing lacks organization and intrahemispheric or interhemispheric synchrony. Notable in the sixth month are a diminution of disorganization and polymorphism and an increase in theta activity and intrahemispheric synchrony. Throughout the seventh month discontinuity decreases progressively, especially in the occipital or occipitotemporal areas. This degree of localization, although built up over the preceding months, is peculiar to the seven-month EEG. Slow waves, mixed with the theta prevalent in the preceding month, predominate.

Several major transitions take place at eight months (Dreyfus-Brisac, 1962, 1964, 1966, Ellingson, 1964a, 1967b). First, a sleep-waking cycle, barely distinguishable near the end of the seventh month, is established, and diffuse reactions to sensory stimuli occur during sleep. These phenomena are discussed in the appropriate sections that follow. Second, bilateral symmetry begins to emerge, initially in the central areas and thereafter in the frontals. Third, activity is now continuous in the waking state, but it is less rhythmic than at 7 months. Some delta and a small amount of alpha and beta activity are present. However, theta frequencies become prevalent again. Finally, the occipital predominance disappears from the waking record, so the topographical pattern is once more diffuse. During the ninth month the only modification

is in the sleep sequence. Indeed, from 8 months through at least the first month after term the waking record remains essentially unchanged (Dreyfus-Bisac, 1966, Ellingson, 1967b).

Why regularity and localization give way to seemingly less mature patterns is not known. Perhaps the apparent regression reflects the emergence of cortical function. A subcortical origin has been hypothesized for EEG activity at earlier stages (Dreyfus-Bisac, 1962, 1966, Ellingson, 1964a, 1967b). More specifically, Ellingson (1964a, 1967b) speculates that the occipitotemporal predominance of activity may indicate origin in the limbic system (a complex system involving parts of the "old brain"). Because she observed potentials primarily in association with body movements, Samson-Dollfus (1955) made the further suggestion that the activity is evoked rather than spontaneous. In any event, the inception of, or an increment in, autonomous cortical activity could mask impulses coming from lower levels.

Observations on the development of the EEG after full-term birth dates from early papers of Berger (1932, 1933), the "father of electroencephalography." Other reports of age changes, some of which included repeated examinations of the same subjects and comparisons of sleeping and waking records, soon followed (Bernhard and Skoglund, 1939, Davis and Davis, 1936, Henry, 1944, Lindsley, 1936, 1938, 1939, Loomis, Harvey, and Hobart, 1936, Smith, 1937, 1938a, 1938b, 1938c, 1939, 1941). By and large, the waking EEG in the first few months of life is like that described above for the eight-month record, diffuseness being emphasized (Dreyfus-Bisac, 1966, Ellingson, 1967b).

A tendency toward concentration of theta activity over the central region in some neonates has been remarked (Ellingson, 1958, 1964a, Smith, 1938a, 1939, 1941), although Dreyfus-Bisac (1966) considers this localization a sign of drowsiness. Open eyes are known to be a fallible criterion of wakefulness in young infants (Ellingson, 1958). There does appear to be a little improvement in regularity, particularly over the central areas, during the early postnatal months. However, no remarkable transformations are seen in the waking record until the third to fourth month. Like the eighth fetal month, this age

marks a significant turning-point. The advent of an occipital "alpha rhythm" and its blocking by sensory stimuli, attention or stress are particularly striking. In addition, refinements in other forms of evoked responses are perceptible (see below).

Whereas alpha band refers simply to a range of frequencies, the designation of alpha rhythm is by tradition reserved for waves of these frequencies that are present in the occipital and parietal areas when the subject is relaxed with eyes closed but are "blocked" by arousal, particularly by visual stimuli (Storm van Leeuwen et al., 1966, Walter, 1963). Using all these criteria except frequency, Lindsley (1936, 1938, 1939) and Smith (1937, 1938a, 1938b, 1939, 1941) reported that the alpha rhythm first appeared over the occiput at about the third month postterm with a frequency of approximately 4/sec and increased in frequency thereafter until late childhood or early adolescence (see Fig. 6). Parietal rhythms, originally faster, increased more gradually.

Some activity in the alpha frequency band is present even in newborn infants (Dreyfus-Bisac, 1966, Ellingson, 1964a, Gibbs and Knott, 1949, Smith, 1938a, 1938b, 1941), but it does not fulfill the other criteria for an alpha rhythm (Kellaway, 1964). For this reason, most electroencephalographers have accepted the view of the development of the alpha rhythm outlined by Lindsley and Smith. A few, however, take exception. Walter (1963) quarrels with a definition of alpha rhythm that excludes the frequency criterion, although the early-appearing alpha frequencies he isolates are not responsive to visual stimulation for several years and hence do not meet another criterion for alpha rhythm. Recently several other investigators have reported considerable fast activity, particularly in the alpha range, in the newborn with the suggestion that the adult form of the rhythm may be intrinsic rather than the product of evolution from slower activity (Churchill, Gisell, and Darnley, 1966, Liberson and Frazier, 1962, Shepoválnikov, 1962, Sidorenko, 1961). To date, however, adequate controls for artifacts from muscle tremor have not been instituted.

There are also indications that the alpha and beta frequencies present in the newborn may be associated with natal circumstances

Fig 6 Development of the alpha rhythm (average frequency per second)

Alpha activity was found to be greatest over the right hemisphere in infants among whom the presenting position of the head was right occiput anterior, transverse or posterior and greatest on the left among those with left occiput transverse or posterior presentation (Churchill et al, 1966). Only 35-45% of newborns have activity in the alpha frequency range (Churchill et al, 1966, Kellaway, 1964), and it disappears from all but the central leads during the neonatal period (Kellaway, 1964). Beta rhythms, found in about the same proportion of infants and especially prominent in the premature, are gone by about 4 weeks (Kellaway, 1964). They recur later in the year (Glaser, 1963).

In the early research on age changes the primary aim was to trace evolution of the dominant rhythms. Few electrodes were used and visual analysis and manual measurements had to be relied upon. Despite these limitations, several trends besides the initially rapid and then more gradual increase in the frequency of the occipital and parietal "alpha rhythm" were discovered. The amplitude of this rhythm increased in some subjects for periods varying from months to years and then declined, so that group averages showed a curvilinear pattern. Wenbach (1938) found frequency to be most highly correlated with brain weight, while amplitude was associated

first with estimated number of active neurons and later with skull thickness. Lindsley (1939) also pointed to the possible role of the closure of the fontanelles in the reduction of recorded voltage. Organization, regularity, and bilateral symmetry were reported to increase rapidly from the fourth month to the end of the first year and more gradually thereafter. The overall range of frequencies, relatively narrow in the first year, was observed to expand, becoming almost as wide as that of the adult by age 10.

These findings were augmented in succeeding studies by using more leads (Dreyfus-Brisac, Samson, Blanc, and Monod, 1958, Ellingson, 1964a, Gibbs and Gibbs, 1950, Novikova, 1961, see also reviews of Dreyfus-Brisac, 1966, and Ellingson, 1967b), and, at times, by automatic frequency analyzers (Bartoshuk, 1964, Corbin and Bickford, 1955, Fujimori, Yokota, Ishibashi, and Takei, 1958, Gibbs and Knott, 1949, Walter, 1963). Judged only by the occipital area, the EEG would be said to approximate adult levels of symmetry by about 1 year, frequency by 10 years, reactivity to stimulation by 12 years, and amplitude by mid-adolescence, although individual differences are admittedly great.

When all regions are explored simultaneously, however, a different developmental picture emerges. Even at 4 years a minor

amount of temporal asymmetry is within normal limits. More slow activity of high voltage is still manifest in the parietal, frontal, and temporal areas at 10 years than is typical of adults. Voltages wax and then wane more gradually in the delta and theta bands, particularly the latter, and especially in the temporal lobes. Regularity, regional differentiation, and stability continue to increase through adolescence. For the most part, beta frequencies come to replace the theta activity predominant in the frontal and temporal areas during adolescence. However, in late adolescence the EEG often still contains a little more temporal theta and is a little less regular in pattern and more susceptible to activation than in adulthood. Continued gradual maturation into the mid-twenties is more common in males than females.

In automatic frequency analysis, the component voltage at each integral and half integral (cycle per second and half cycle per second) is measured and graphed. The integrated voltage from one or more regions or pairs of homologous regions may be assessed individually or pooled. Because analysts cannot tell fact from fiction, artifact-free sections of record should be used. The operator is also the one who must separate sleeping, drowsy, and waking segments, but not all have done so. This may be one reason why a higher incidence of slow frequencies among infants and children is found with automatic than with manual analysis. On the other hand, the analyzer detects frequencies that are hidden from the eye by the masking of some smaller components by larger ones, so the underlying spectrum is more faithfully reproduced.

Although relatively few automatic analyses have been done on a normative developmental basis, the results are consistent. The range of frequencies observed is like that from manual measurement, and the overall trend is similar. To quote Gibbs and Knott (1949), whose pioneer work was based on summated activity from the left frontal, parietal, occipital, and temporal areas: "With each successive year the peaks of component voltage move further out toward the high-frequency end of the spectrum. Up to the end of the first year this acceleration only extends the shoulder of the low-frequency peak out to nine cycles." A "hump" appears on the shoulder of the low-

frequency peak in the 9 cps range at 2 years. This hump increases in size and complexity until 6, when the balance of component voltage swings to the faster side. Then a single, strong peak emerges and increases in voltage to 11 years. At the same time voltage in the very slow bands is declining and that in the fast ones rising. Analysis of voltages from the right and left parieto-occipital area yielded comparable results (Corbin and Bickford, 1955).

As has already been indicated, the pattern of predominant frequencies looks somewhat different at the lower end of the age continuum in automatic than manual analyses. Instead of a predominance of the theta band with lesser amounts of delta activity, the concentration of voltage in very slow frequencies is as high or even higher at 2 years.

Bartoshuk (1964) found reliably less slow activity and more fast activity in the waking than sleeping records from both the frontal-precentral and parietal-occipital areas of newborn infants. Both waking and sleeping samples showed more slow activity (1.4-6.0 cps) in the frontal-pericentral region and more beta activity in the parietal-occipital.

Ontogeny of Sleep Patterns in the EEG

Except for Smith's (1938) "Preliminary Observations on the Pattern Sequence during Sleep" in infants and young children, the development of the electroencephalographic concomitants of the sleep-waking cycle received no systematic attention until almost 20 years after Berger's (1929) original paper on the EEG. Within the next decade, however, correlative studies of several sorts had coalesced to make research on sleep active, exciting, and productive.

Impetus for clinical studies of sleep, which proved to be the most valuable activator of abnormalities in children's EEGs (Fois, 1961, Paine and Oppé, 1966), came primarily from Gibbs and Gibbs' (1947, 1950) reports on the diagnostic value of sleep recordings. Concurrently, the normative data basic to clinical evaluation began to accumulate. The resurgence of interest in infancy that had become apparent by the early 1950s (Dreyfus-Brisac and Blanc, 1956, Dreyfus-Brisac and Monod, 1956, Kellaway, 1952, Kellaway and Fox, 1952, Schaper, 1953a, 1953b, Schroeder and Heckel, 1952) was signaled first by new data

on full-term newborns while asleep, drowsy, and awake (Hughes, Eheman, and Brown, 1948, Hughes, Eheman, and Hill, 1949) and then by observations on premature infants under similar conditions (Hughes, Davis, and Brennan, 1951). Detailed analyses that still constitute the standard reference on normal sleep patterns from birth through 60 years were included in Volume I of the Gibbs' *Atlas of Electroencephalography* (1950). Although their terms for sleep stages are not consistently used by all investigators (see discussion in Lindsley, 1960), and later research, particularly with premature infants, has somewhat modified their conclusions, delineation of the notable features of the Gibbs' sequence will provide an overview of age changes and make fitting more recent data on young subjects into their niches easier.

According to the Gibbs, seven stages of sleep can be discriminated in the adult EEG: drowsiness, very light sleep, light sleep, moderately deep sleep, deep sleep, early morning sleep, and arousal. The patterns are topographically more differentiated than those of the waking record and more complex in their development, yet individual differences at any given age are less marked. Across the age span entry into and arousal from sleep show the greatest changes. In infants under 1 month, the Gibbs could distinguish mainly light and deep sleep. Subsequent workers agree that it is difficult to discriminate phases of sleep or sleep from waking. However, they have demonstrated an incipient differentiation of sleep from wakefulness during the seventh fetal month in the form of a slight increase in the amplitude of slow waves. This shift becomes more pronounced at 8 months, when superimposed low-voltage fast activity is common. Beginning in the second month steady, high amplitude waves are seen in drowsiness, their frequency increasing from 2–4/sec to 4–6/sec by 1 year. This activity has since been called "hypnagogic" (Kellaway and Fox, 1952) and "oscitant" (Ellingson, 1967b). During the second year the incidence of these waves begins to decline, and they appear in bursts rather than runs. At the same time fast activity (20–30/sec), first present in the second half of the first year, increases in amount. Paroxysmal slowing remains common through 14 years, but fast activity decreases rapidly after 2 and is gone by 10, when the

adult pattern of flattening with some slowing becomes typical.

The biparietal humps characteristic of very light sleep throughout the rest of the life span begin to appear in the last half of the first year and reach adult incidence in the second. By about 3 months the spindles of light sleep, present even in the first 2 months, also are as prominent as at later ages, although they are not as well formed until 3 years.

Whereas the Gibbs characterized deep sleep as a state in which almost all activity is very slow (0.5–2.0/sec) with a little superimposed fast activity, others have since found a recurrent pattern in this stage, the *tracé alternant* (see reviews in Dreyfus-Bisac 1966, Ellingson, 1967b). Bursts of irregular slow activity mixed with somewhat rhythmic 4–6/sec waves with superimposed faster low-voltage activity alternate with periods of comparative electrical silence. This pattern is first seen during the last month of gestation.

Before 2 months it is difficult to differentiate any specific signs associated with spontaneous arousal from sleep (as distinguished from applied stimulation). Then continuous high amplitude slow waves are present in about half the subjects. The incidence of this pattern increases during the first year, remains constant through 6 years, and then declines to disappear by 20. While it is present, frequency increases and amplitude decreases somewhat with age. Normal adults never show this type of slowing, but return quickly to the waking pattern. An intermediate phase of paroxysmal slow activity on arousal, maximally present at 10–14 years but occasionally seen as early as 3 years, is found in a small proportion of adults.

The discovery of a new phase of sleep during the mid-1950s considerably altered the subsequent course of developmental work on sleep stages. Observations on young infants revealed alternations between quiet sleep and periods of body and eye movements (Aserinsky and Kleitman, 1955), and recurrent phases were found during deep sleep in adults in which a desynchronized EEG, much like that of the aroused, alert state, and accompanied by rapid eye movements (REM) replaced slow waves (Aserinsky and Kleitman, 1953, 1955, Dement and Kleitman, 1957). Both developmental and comparative studies with lower animals indicated that the REM

state was a primitive form of sleep (Jouvet, 1961, 1963, see review of Snyder, 1965, for references on a wide variety of species). Meanwhile neurophysiologists had been exploring the role of the reticular system in sleep and waking (Lindsley, Schriener, Knowles, and Magoun, 1950, Magoun, 1954, Moruzzi and Magoun, 1949), and a hierarchy of reticular centers for arousal, REM, and quiet sleep were outlined (Moruzzi, 1964). An important supplement to the electrophysiological researches on sleep was provided by investigators concerned with activity cycles, psychophysiological state, and control of the conditions under which stimulation is administered. They used observational and polygraphic measures of respiration, heart rate, body and eye movements to scale the sleep-waking continuum (see reviews in Crowell, 1967, and Steinschneider, 1967). To refine the definitions of phases of the sleep-waking cycle or to have independent measures, EEG and polygraph recording and observation were combined (Delange, Castan, Cadilhac, and Passouant, 1962, Goldie and Van Velze, 1965, Parmelee, Wenner, Akiyama, Stern, and Flescher, 1967, Parmelee, Wenner, Akiyama, Schultz, and Stern, 1967, Petre-Quadens, 1966, 1967, Roffwarg, Dement, and Fisher, 1964, Roffwarg, Muzio, and Dement, 1966, see also reviews in Dreyfus-Brisac, 1964, and Ellington, 1967b).

As work using several techniques of assessing waking and sleeping states progressed, it was demonstrated that REM sleep is characterized not only by fast, low-voltage, desynchronized EEG activity and rapid eye movements, but also by irregular heart rate and respiration, and a lack of both neck muscle tone and phasic movements of the face and limbs. The *tracé alternant* is present during quiet sleep, respiration and heart rate are regular and slower, and, while tone returns in the anterior neck muscles, other muscles are relaxed and few body movements occur. These two stages of sleep can be distinguished as early as the seventh fetal month, but the distinction is difficult. With increasing age, both the EEG and other patterns become clearer (Parmelee, Wenner, Akiyama, Stern, and Flescher, 1964). For example, muscle potentials are present during REM sleep in the 7-month fetus, whereas by term EMG

(electromyograph) activity usually disappears in active sleep (Petre-Quadens, 1967).

The proportion of active sleep declines steadily from the seventh fetal month through 3 months post-term, while quiet sleep increases more gradually, the remainder of the time is accounted for either by transitional sleep or less time spent in sleep (Parmelee, Wenner, Akiyama, Schultz, and Stern, 1967, Petre-Quadens, 1967). However, computer coding of EEG and polygraph records reveals some increase in active sleep through the eighth fetal month, more transitional sleep, and a greater and more regular decline in the latter than in active sleep. The absolute and relative amount of REM sleep decreases throughout the life span (Roffwarg, Dement, and Fisher, 1964, Roffwarg, Muzio, and Dement, 1966). In contrast, the time spent in quiet sleep increases a little during the first 2 years and does not begin to decline to any extent until 10-13 years.

The progressive differentiation of sleep phases has been interpreted as a reflection of the maturation of the functional divisions of the reticular formation (Parmelee et al., 1964). The pontine reticular substance is the primary center for active sleep, the medullary for quiet sleep, and the mesencephalic portion for arousal (Moruzzi, 1964). A progressive shift from primarily pontine to medullary control with age is suggested by the decreasing predominance of active sleep and the increase in quiet sleep, while maturation within both regions is indicated by the fact that each phase becomes better defined. Improvement in the capacity to sustain wakefulness, a trend very noticeable even between term and the third postnatal month, suggests increasing activity not only in the mesencephalic segment but also at higher levels and greater interaction within the central nervous system.

Ontogeny of Evoked Responses

Although the waking and sleeping patterns thus far described must be influenced in some measure by a conglomerate of external as well as internal stimuli, they are referred to as spontaneous rhythms. Evoked responses are potential changes induced by discrete sensory stimuli, usually deliberately applied. They are superimposed on background activity, complex in wave form, and time-locked to stimu-

lation, responses occurring at both the onset and termination of the stimulus. As yet "off" responses have received less systematic attention than "on" responses, especially in developmental studies. Because ongoing activity often masks evoked potentials, they may not be detected without the aid of some kind of summing or averaging device. Electronic techniques in which variations in voltage over a period subsequent to stimulation are repeatedly stored, algebraically summed, and then averaged are now widely used. Brain waves that are not associated with the timing of the stimuli should be randomly distributed among positive and negative values and thus will cancel each other out to yield a sum of zero. On the other hand, responses that are temporally related to stimulation will be regularly positive or negative at given points in the succeeding time interval. Statistical as well as experimental controls are essential in work with evoked potentials. These and other aspects of methodology have recently been reviewed (Ellingson, 1967a, 1967b), and several current summaries of the developmental literature on evoked potentials are also available (Ellingson, 1964b, 1967b, Golding, Sugaya, and O'Leary, 1964).

Some evoked responses, or segments of them, are nonspecific in that they are elicited by stimuli of more than one modality, for example, both audition and vision. There has been controversy about the existence of truly specific responses for a particular sensory modality. Whether or not the components of the induced wave forms are different for different senses is still unsettled, but there is good evidence for specificity of cerebral region for both visual and somatosensory stimuli. To date, specific auditory responses have not been demonstrated in the human being, probably because the primary projection areas are so deep that surface electrodes are inadequate for detecting them. In addition to being utilized in research on the cortical projection of sensory inputs, evoked responses have been useful in studying interaction between neural systems, the influence of stimulation on states of consciousness, and other aspects of neurophysiological function. They also offer another means of assessing the physiological development of the nervous system.

Nonspecific responses do not appear until about the last month of gestation. At this time

auditory stimuli may flatten ongoing activity, intensify and then flatten sleep potentials, or produce topographically diffuse bursts irregular in wave form (Dreyfus-Brisac and Blanc, 1956, Ellingson, 1958, 1960, Engel, 1961). After the third postnatal month either somesthetic or auditory stimuli will *increase* the amplitude of sleep waves or evoke sharp, slow potentials of negative polarity. During deep sleep the latter may be followed by a series of potential changes called the K-complex, a typical response to auditory stimulation during sleep in the adult. By the end of the first year, several other responses to auditory stimuli are observed: diphasic high-amplitude potentials over the vertex, slow waves of moderate amplitude in frontal leads, and high-voltage slow waves over the occiput (Dreyfus-Brisac and Blanc, 1956, Ellingson, 1958, 1964a).

Because hearing cannot be tested in infants and young children by conventional audiometry, electroencephalographic reactions to auditory stimuli have also been the subject of considerable clinically motivated research (Appleby, 1965, Barnett and Lodge, 1966, 1967a, 1967b, Debyshue, Fiasei, McKernott, and Bridge, 1956, Ortiz-Estrada, Deutsch, and Hernandez-Orozco, 1963, Rapin, 1964, Wedenberg, 1956, Weitzman, Fishbein, and Graziani, 1965, Williams and Graham, 1963). Otherwise, developmental work has been concentrated on specific responses to visual stimuli, and nonspecific responses in general as well as specific responses to somesthetic stimuli have been neglected. This fact is somewhat surprising in view of anatomical data showing that the somesthetic area is better developed at birth than other sensory areas (Conel, 1939) and at least one report indicates that in newborn infants nonspecific responses are most likely to occur to somesthetic stimuli. At birth auditory stimulation is only moderately effective, and nonspecific visual responses are relatively rare, although specific ones are present long before term.

If even brief flashes are presented, specific visual responses can be detected in the occipital area. When these responses first appear is not known, but they have been observed in the youngest premature infants thus far tested, one of 24 weeks (Engel, 1964) and another of 28 weeks (Ellingson, 1960). In adults the specific visual response is polypha-

sic, consisting of both positive and negative components, but as first seen in the fetus (premature infant) it is a monophasic negative wave. An initial positive wave is added sometime during the last 2 fetal months. "All normal full-term human newborns display visual evoked responses" in electronically averaged recordings, and 98% show at least the diphasic pattern (Ellingson, 1967b, p. 83). A double positive phase or a positive-negative-positive pattern is seen in most (Ellingson, 1967b, Ferriss, Davis, Dorsen, and Hackett, 1967). One of the most outstanding features of the neonatal response is its "fatigability" (Ellingson, 1960). Perhaps this term is misleading in its implications, but it reflects well an observer's subjective feeling when he attempts to elicit responses in close succession (Eichorn, 1951). Unless approximately 1 second intervenes between stimuli, a response to the second stimulus is unlikely. Longer intervals are required for premature infants.

With increasing age the variability of the specific visual response in both amplitude and wave form decreases (Ellingson, 1960), and successive responses ("following" or "driving") can be elicited at progressively closer intervals (Eichorn, 1951, Ellingson, 1967b). Other changes include the appearance of additional negative waves—one before the two positive waves and several "late" ones that extend the temporal course of the response beyond 250 msec—and alterations in regional distribution, latency, and voltage (Ellingson, 1960, 1966, Engel, 1964, 1965, Engel and Butler, 1963, Ferriss et al., 1967, Hisek and Mares, 1964).

Until about 3 months all components of the visual evoked response are confined to the occipital region. After that age the later components can be detected as far forward as the central area, so these negative waves may be considered a nonspecific response. The average time elapsing between presentation of a stimulus and the greatest amplitude of the major positive wave is about 220 msec

6 weeks before term. Latency decreases rapidly and almost linearly to about 190 msec at full-term. The decrement is still rapid but decelerating through the third month, when the mean is about 100 msec. Thereafter a gradual decline continues to 14-18 weeks, when the adult latency of 80-90 msec is approximated. The data just cited are Ellingson's (1960, 1964a, 1966), those of other investigators differ somewhat in absolute means and in postnatal trends (Engel, 1961, Engel and Butler, 1963), including a possible decrease in latency through 4 to 8 years. At birth voltages (amplitudes) may be as high as in older children and then decrease briefly (Ellingson, 1964a). From 1 month to 7 or 8 years, however, the amplitude of all components increases markedly (Dustman and Beck, 1966). The subsequent decline in voltage is temporarily reversed around age 13 to 14 and then resumes until amplitudes like those of young adults are reached at 17 to 19 years (Dustman and Beck, 1966).

Overview

Many intriguing parallels can be drawn between the development of spontaneous and evoked potentials, the anatomical and biochemical maturation of the brain, and behavioral development (Eichorn, 1963, Eichorn and Jones, 1958, Golding, Sugaya, and O'Leary, 1964, Purpura, 1961a, 1961b, Scheibel and Scheibel, 1964). With a few exceptions (Purpura, 1961a, 1961b, Scheibel and Scheibel, 1959, 1961, 1962), however, these remain in the realm of speculation. One message does seem clear from all types of physiological data: the perinatal period is one of rapid, complex, and often temporary changes in most functions, and prediction to subsequent status is usually poor. Probably the developmental psychologist is expecting too much when he searches for significant associations between behavior at this time and at later stages.

PART II

INFANCY AND EARLY EXPERIENCE

5. Human Infancy: A Bibliography And Guide¹

WILLIAM KESSEN

MARSHALL M. HAITH

PHILIP H. SALAPATEK

As men and as psychologists, we have long been concerned with beginnings. Tiedemann, whose words opened the modern study of children ("... it is by experience and exercise that we learn to be served by our senses and to perceive correctly; observations made on men ... found in the wild ... have shown that the faculties of mind develop bit by bit and one after the other"), laid out many of the problems that direct the work of men who nowadays study human infants. What does the newborn infant bring, in body and behavior, to his first encounters with the world? How do "experience and exercise" modify the infant's behavior? To what degree does the baby's later behavior *emerge* from an innate potential? When we observe the young child, how much do we see the species—the child as representative of Man—and how much do we see a person, individual and perhaps unique? How does the world of the adult, physical and social, come to be represented in the mind of the child? How well can we predict the future course of a person's life from our knowledge of his infancy? Finally, the most durable of questions, what methods can we validly use to understand the infant; what are the windows on the baby's mind? To be sure, the rhetoric of the psychology of infancy has changed often but the organizing themes of study have remained remarkably stable. What is the *initial state* of the newborn's behavioral system? What events and processes determine the *transformation* of the initial state?

Certainly, the study of the infant cannot be confined to beginnings. We see the baby, in the first 18 months of life, undergoing continuous and rapid change. Whether one sees

the newborn child as neurologically insufficient (Flechsigs, 1920), cognitively confused (James, 1890), narcissistic (Freud, 1905), solipsistic (Piaget, 1927), or merely ugly (Hall, 1891), the distance between the new child and the walking, talking, socially discriminating, and perceptive person whom we see hardly 500 days later is awesome. Hall, for all of his interest in observing development, found distasteful the baby who arrives with its "monotonous and dismal cry, with its red, shriveled, parboiled skin, ... squinting, cross-eyed, pot bellied, and bow legged" (Hall, 1891). James, more sensitive to the psychological issues, speaks of "the baby, assailed by eyes, ears, nose, skin, and entrails at once, [who] feels that all is one great blooming, buzzing confusion" (James, 1890, p. 488). Compare the description of a somewhat advanced 18-month-old:

... this little girl could walk up and down stairs without climbing but in an almost adult manner, and could be trusted on the stairs alone. She could climb up to stand on a chair,

¹ Many zealous searchers worked to construct the bibliographic basis of the present chapter—among them, John Dow, Anne-Marie Leutzendorff, Marion Kessen, Robert Milstein, and Linda More. Lyn Wickelgren's review of the literature on vision was essential. All the many versions of the chapter were typed by Jayne Rightner and checked by Keith Nelson. Grants to Professor William Kessen from the United States Public Health Service (HD-0890) and the Carnegie Corporation of New York and to Professor Marshall M. Haith from the United States Public Health Service (HD-2680) supported the research represented here.

could seat herself at table, could jump off a step, kick a ball. . . She helped to dress herself, taking off some of her garments unaided, including shoes and socks. She put away toys, with encouragement, and could be trusted with breakables. . . she was talking freely and clearly in short sentences. . . She named ten pictures . . . and gave her first name but not her second name . . . she scribbled freely with a pencil, made strokes and attempted the circle (Griffiths, 1954, p. 97)

Unhappily, we know far less of the middle and end of this period of startling change than we know of its beginning. The majority of studies of the human infant—if we take the upper bound of infancy to be that time in the middle of the second year when vocabulary explodes (Lenneberg, 1967)—is directed to an understanding of the first days and weeks of life. Technical knowledge of newborn behavior, although insufficient to our wish, greatly exceeds our knowledge of the 2-, 6-, 12-, and 15-month-old child. For reasons rooted as much in the easy accessibility of newborn children as in theoretical demand, the bibliography of studies on infancy is largely a bibliography on the study of the newborn infant.

Even so, the growth of research on infants over the past 60 years has been prodigious. Baldwin's (1901) listing had only a handful of papers on infancy despite his desire to reach back in time and across national boundaries. As late as 1933, Hurlock, in describing "experimental studies of the newborn," cited 76 references. Pratt (1954), in his chapter for the second edition of *Carmichael's Manual*, surveyed about 500 studies of the very young child. The bibliography of the present chapter lists upward of 2000 titles. Clearly, the literature of infancy is beyond summary in detail. Rather, the pages that follow represent an attempt to disentangle and differentiate the problems, methods, prejudices, and theories that have determined the course of research on the young infant in the twentieth century. The program of the chapter, then, contains the following elements: (1) a brief treatment of theoretically general issues; (2) a sketch of methods used in the study of the young child; (3) an illustrative guide to the several different ways in which investigators have at-

tempted to understand the infant, (4) a more narrowly defined treatment of three aspects of the infant's behavior that are of particular interest to us, and (5) a bibliography of early infancy comprehensive enough to carry the student as far as he wants to go in the research literature

SEVERAL GENERAL THEORETICAL ISSUES

It has become a platitude to say that selection of problem for study, method of data collection and analysis, theoretical expectations, and even the researcher's friends are determined by the same variables. Similarly, somewhat loosely defined *schools* of the psychology of infancy exist, and the empirical literature can be organized to emphasize the distinctions that exist among various conceptions of the child. In our search for expository clarity, we have separated somewhat discussions of theory, method, and findings, but the divisions are at best artificial. The psychology of infancy does not represent a full matrix in which each available method has been applied to each available observational opportunity and the outcome evaluated in the light of each theory. To be sure, some attempts have been made to state encompassing positions (e.g., Preyer, 1880, 1882, Stern, 1914; Koffka, 1924; Gesell, 1928, Watson, 1928; Freud, 1940; Piaget, 1946) but, by and large, the study of infancy is a loose confederation of ideas about babies and about psychology. All theories of the infant have had something to say about environment and behavior but even conceptions as fundamental as *stimulus* and *response* do not have commonly shared definitions. Moreover, students of infancy have given vastly more attention to definition of the response—*measures of the infant*—than they have to definition of the stimulus—*the nature of the environment*.

The Nature of the Environment

Whatever their research concern, all psychologists must attend to the issue commonly known as the *definition of the stimulus*. The clarification of this problem may be more troublesome for students of the very young child than for their colleagues who observe adult forms. The infant is, in fundamental ways, incomplete and the use of adult cat-

egories of the environment to define the stimulus field of the child can be misleading (consider, for example, the problem of color perception discussed by Pratt, 1954). Moreover, limitations in the behavioral repertoire of infants—for example, the absence of language—make difficult the establishment of the converging operations that permit us to make confident definition of the environment of adults.

Wolf (1957) proposed that in trying to make sense of the infant's environment, useful rough distinctions could be made among *stimulation*, *reality*, and *world*. *Stimulation* represents the organization of the environment into the abstract, precise, and often quantified dimensions of physics and sensory physiology. The study of auditory threshold in which careful control is maintained over the stimulus and the definition of visual stimuli in terms like *luminence* and *wave length* are cases in point. A large and increasing number of studies of infants attempt a definition of the infant's environment as stimulation. *Reality* encompasses the world of common objects. The environment is defined in the categories that most adults, whether psychologists or not, find comfortable. The infant is presented with a *ball*, a *dangling ring*, a *doll*, or a *staircase*. Clearly, such a definition of the environment blends out of *stimulation* and shares with physically defined stimuli the characteristic of remarkably high agreement among adults in the circumstances of appropriate application of the terms. But the environment defined by the usual adult is not the environment of the physicist-physiologist and, more consequentially, it need not be the environment of the infant. In writing of the infant's *world*, Wolf noted that the child must be considered to have his own theory of the environment and that we may make grossly unjustified inferences about the child's world if we speak of presenting him with a *mother's face*, a musical *phrase*, or a complicated *figure*. A future psychology of infancy will permit us to make statements about the child's ordering of his experience with more assurance than is now possible, and, in the meantime, empirical studies of the infant should be read with an eye on their definition of the environment. Kagan has pointed out the dangers of giving normal adult modes of thought a favored position in our attempts

to comprehend the mind of the child:

It is threatening to abandon the security of the doctrine of absolutism of the stimulus event. Such a reorientation demands new measurement procedures, novel strategies of inquiry, and a greater tolerance for ambiguity (1967, p. 141).

The difficulties of defining the environment of the infant will appear several times in the present chapter; in particular, the discussion of vision illustrates the vagaries of the issue.

Measures of the Infant

The definition of the response is hardly a less complicated issue than the definition of the stimulus, but the literature of infancy appears to show more regularity in the use of behavioral categories than it does in the definition of the environment. The imbalance partly reflects a recognition that precision in psychological analysis and comparison among different studies rest on the reliability of observations and partly reflects the fascination with method and measure that characterizes academic psychology. The recent history of infancy studies may, with only mild unkindness, be seen as largely representing an increase in the precision with which we measure the behavior that used to be measured less precisely. As will be seen in a later discussion of the several views of infants, there is substantial variation in the procedures and metrics of behavioral analysis; nonetheless, a brief listing of commonly used categories of measures of the infant may put the research literature into preliminary organization.

First, some old home truths. Measures of the infant serve several, sometimes mixed, functions, chief among them the *establishment of developmental norms*, the *assessment of individual variation*, and the *diagnosis of process or structure* (i.e., the measure of the interaction between infant and environment). Thus heart rate may be seen as a measure of cardiac function that changes systematically over the first months of life, or as an indicator of stable differences from one infant to another, or as a measure of sensory sensitivity and attention in the infant. Although the several functions of measure are by no means incompatible and a rare study will give them all proper due, there is usually a

clear emphasis in particular studies on one function or another.

Physical Growth. After birth, infants continue the growth rates characteristic of the fetal period and then, near the end of infancy, enter the period of stable linear growth that will be characteristic until the spurt of adolescence. In the first 2 years, children go from about 20 inches in length (30% of AS [adult status]) to about 34 inches (50% of AS), and from a brain weight of $\frac{3}{4}$ pound (25% of AS) to a brain weight of almost $2\frac{1}{2}$ pounds (75% of AS). Students of physical growth, struck by the regularity and possibility of quantification of physical growth in children, have devoted great energy to the study of anatomical change in the first years of life. Sophisticated procedures have been used to assess height, weight, relation of limb size, variations in patterns of tissue growth, ossification, among others (see, e.g., the discussion of growth in Falkner, 1966). The development of the brain has been of particular interest to students of growth (especially Conel, *passim*). The rate of growth in brain size is at a maximum near birth, and by age 6 children have achieved almost all of their adult brain size. No other anatomical

system changes so quickly. Much of the change in brain weight can be ascribed to postnatal myelination and gliosis. Although myelination of all cranial nerves save the optic and olfactory is complete at birth, only a relatively small proportion of cerebral neurons (primarily in the afferent projection systems) has been myelinated. Moreover, changes in the nervous system are rapid enough to make the brain of the 2-year-old child hardly discriminable in histological characteristics from the adult brain (Dekaban, 1959; Gruner, 1962; Kennedy, 1961). Figure 1 records the changes that take place in myelination and gliosis during the first 2 years of life.

Normative Measures. A large number of normative measurements have been made of physical growth in the fetal, newborn, and young infant (see, e.g., Bayley and Davis, 1935; Thomson, 1956). Merminod (1962) and Falkner (1966) present fairly comprehensive reviews of work on external measurements, bone age, water, fat, and protein composition of the body, as well as currently available data on variation in early physical growth that can be assigned to variations in nutrition, variations in social environment, and sex differences. A persistent and striking finding is the individual regularity of certain aspects of physical growth. Although the several measures of physical status in newborn babies are not highly intercorrelated (Bakwin and Bakwin, 1934; Carter and Krause, 1936) and no measure of newborn status correlates highly with terminal size, within a few weeks *length* at least has become a reliable indicator of adult stature. Bayley (1946) found correlations above .50 between length at 3 months and height at 18 years in her California sample and her data are congruent with British data (Merminod, 1962) in finding that the height of the 2-year-old child (who is almost exactly half his adult height) correlates at about .70 with his ultimate height. Regularity of this sort is not characteristic of any other physical growth measures, and it is, of course, not even approached by any measure of infantile behavior.

Effects of Nutrition. It has been known for some time that improved nutrition will increase rates of growth (e.g., Greulich, 1957) and may be critical to understanding the striking changes in the physical dimensions of human beings through the ages (Tanner,

Fig. 1. The beginning and end of myelination-gliosis in neural development. The process is at its maximum during the times shown by broadened lines: (1) Auditory nerve; (2) internal capsule; (3) pyramidal tract (mid-olvar level); (4) pyramidal tract (crus cerebri); (5) optic tract; (6) cerebellar subcortical, central; (7) cerebellar subcortical, peripheral; (8) cerebral subcortical, central; (9) striae of striatum; (10) corpus callosum; (11) cerebral subcortical, occipital; (12) cerebral subcortical, frontal. (From Dodgson, 1962, p. 207.)

1962) Correspondingly, undernourished babies (e.g., those born during wartime) are small and grow slowly (Dean, 1951). Recently, chiefly through large-scale investigations by agencies such as the *Centre Internationale de l'Enfance*, systematic studies have been made of the effects of generalized malnutrition, recovery from malnutrition, and the effects of malnutrition on intellectual as well as physical growth. Work with African children suffering from kwashiorkor (Dean, 1960) suggests that infants show sharp gains in weight and height when given calorically sufficient supplementary diets but that their physical measurements never come up to standard. Dean (1962) even suggests that there may be a falling away from expected development after age 4 even though the children continue an adequate diet.

Effects of malnutrition on cognitive growth cannot be readily documented. Large-scale studies of malnourished African children are only now under weigh, but the work of Cravioto (1969) in Latin America has suggested that prolonged malnutrition decreases intellectual competence in the school-age child. Available evidence does not suggest, however, that short-term and moderate malnutrition—again, in wartime babies—has significant effects on intellectual development. The effects of social environment on growth are hard to dissect from genetic variation. However, studies by Graffar (1962) and Acheson (1959), among others, indicate that the children of the higher social classes are taller and heavier than working-class children by the second or third year of life.

Racial Variation. Studies of racial difference are almost hopelessly confounded with issues of nutrition, early environment, and cultural variation. Earlier studies of indigent blacks (e.g., Bakwin and Patrick, 1944), showing that they were smaller and lighter than whites, have been corrected by studies of family children (e.g., Scott, Cardoza, Smith, and DeLilly, 1950; Crump, Horton, Masuoka, and Ryan, 1957) that show insignificant differences between blacks and whites on initial measures and early development. On the other hand, there is some evidence (Falkner, Pernot-Roy, Habich, Sénécal, and Massé, 1958) that African blacks are advanced in skeletal maturation at birth. Continuing studies of the *Centre Internationale de l'Enfance*

(cited by Falkner, 1966) suggest that there may also be racial differences in rates of growth and patterns of growth during the first four years of life.

Sex Differences. Differences between boys and girls in physical growth in the first years do not submit to easy generalization. Generally, boys are somewhat larger in external measures and show greater variability in development (e.g., Bakwin and Bakwin, 1934; Garn and Rohmann, 1960). Boys show higher mortality (Childs, 1965) and a greater susceptibility of their skeletal growth to variations in the environment (Acheson, 1966). The greater variability and vulnerability of boys, even in the first years, has been remarked by several authors (see Kagan and Kogan, Chapter 18 of this book). Douglas and Blomfield (1958), however, present evidence in support of a contrary conclusion. They show, for example, that girls in families of "nonmanual" workers grow relatively faster in the preschool years than their male peers and that girls from lower-class families are more likely to be admitted to the hospital. Bayley (1954) has shown that, in spite of the demonstrated more stable skeletal maturation of girls, terminal height can be much more reliably predicted from boys' length in the first years of life than can the terminal height of girls. It may be, as Bayley has suggested, that growth is under the control of different variables at different ages and that these variations interact with sex. Acheson (1962) has pointed to the probable important effect of timing of environmental variation on growth, particularly as the variation may be mediated by hormonal changes.

Physique and Behavior. Studies of interrelations among measures of physical status and behavior in young infants (e.g., Crowell, 1962) have found little or no significant relation between anatomical and behavioral measures, a finding congruent with recent careful work on the relation between physical measures and intelligence in older children (e.g., Lenz' note in Merminod, 1962, p. 156f.).

Physiological Measures. At least since Canestrini's (1913) ingenious use of cranial blood pulsation as an index of sensory functions in young infants, physiological measures have been used by students of infancy. Respiration and heart rate were often part of

early investigations, developmental studies of the electroencephalogram began to appear shortly after the procedures had been developed for adults (e.g., Dreyfus-Bisac, Flescher, and Plassart, 1962, Engel, 1963, Smith, 1958), evoked potentials both auditory (Barnet and Goodwin, 1965) and visual (Ellingson, 1960, Dustman and Beck, 1966) have been assessed in infants, and, at one time or another, the behavior of babies has been related to stomach contractions (Carlson and Ginsburg, 1915), body temperature (Grossman and Greenberg, 1957), skin color change (Simons, 1925), vasodilation in the skin (Richmond and Lustman, 1955), basal skin conductance (Weller and Bell, 1965), skin potential (Wenger and Irwin, 1936, Stechler, Bradford, and Levy, 1966), and electroencephalography (Barnet, Lodge, and Armington, 1965), among others. The use of physiological measures in the study of early development has been reviewed by Eichorn (1963, 1968) and by Steinschneider (1967).

The Uses of Heart Rate Apart from their intrinsic interest to students of physiological development (Phillips, Agate, Silverman, and Steiner, 1964, Shock, 1966, Lipton, Steinschneider, and Richmond, 1966), physiological measures have served the study of developmental change, of individual variation, and of psychological process. In recent years, the analysis of cardiac response—typically heart rate—and its relation to stimulation, on one hand, and to other measures of the baby, on the other, has become the physiological measure of greatest interest to American investigators. Measures of cardiac activity can illustrate the remarkable range of use of physiological indicators in the study of infants.

Bridger and Reiser (1959) extended procedures used with adults in a study of the cardiac response of 40 children in the first week of life to air-stream stimulation of the skin. They found that the cardiac response to stimulation (acceleration of heart rate or deceleration) bore a strong relation to prestimulus heart rate. Moreover, it was possible to plot, for each baby, a regression line relating initial level of heart rate and response to stimulation. Certain characteristics of these regression lines—particularly that value of initial heart rate at which the stimulus produced neither acceleration nor deceleration—

were remarkably consistent in 15 babies who were tested on two different days. The operation of such a *law of initial value* in cardiac response to stimulation (a law that governs other measures of infants, both physiological and behavioral) requires that studies which use cardiac acceleration or deceleration as indicators of underlying psychological process be interpreted with care. Richmond and his colleagues have analyzed the parameters of cardiac response in 16 newborn females in some detail (Lipton, Steinschneider, and Richmond, 1961, Richmond, Lipton, and Steinschneider, 1962, Steinschneider, Lipton, and Richmond, 1964). The usual finding of a negative relation between prestimulus measures of the *magnitude* of the cardiac response and response to stimulation was obtained. Moreover, stable individual variation in slope of the regression line relating initial rate and response was demonstrated as well as individual variation in the newborn's capacity to return to prestimulus levels. Four temporal parameters (e.g., time to peak magnitude) were found to be generally independent of prestimulus characteristics and generally stable as a measure of individual variation. By and large, the several measures of cardiac functioning were not highly interrelated. In a follow-up study of 14 infants through the first 5 months of life Lipton, Steinschneider, and Richmond (1966) noted that, in addition to other maturational changes in cardiac response, infants at 10 weeks and 5 months of age showed higher intercorrelations of response measures than were typical for newborn infants. Again, as is commonly found with other measures of infants, there is a tendency for cardiac functioning to become stabilized during the first months of the infant's life.

Psychophysiological measures, including heart rate, have long been proposed as indicators of underlying psychological process (see Peiper, 1963, for a summary of early work). Perhaps the simplest of these is as a sign that the organism has detected an environmental change, for example, the infant's detection and discrimination of sounds has been assessed by variations in cardiac response (Bridger, 1961, Bartoshuk, 1964). Changes in heart rate have also been used as indicators of habituation (e.g., Keen, Chase, and Graham, 1965) and of learning (e.g.,

Pohkanina, 1961) A variety of physiological measures has been used in studies of the infant's changes from asleep to waking—the heavily engaged problem of infantile *state* Prechtl (1968), for example, described polygraphic procedures for recording simultaneously four channels of electroencephalography, six channels of electromyography, respiration, heart rate, and two channels carrying human judgment in the investigation of newborn state and the transition between different states of the young organism Achievement and need in physiological measurement of the infant are revealed in Prechtl's assertion that "not less than 16" parameters of neurophysiological and other functions must be assessed in order to comprehend the problem of behavioral state

Recently, interest has been shown in the use of physiological measures (again, particularly changes in heart rate) as measures of *attention* in young infants Graham and Clifton (1965) have reviewed the literature linking heart rate changes to changes in attention Lewis, Kagan, Campbell, and Kalafat (1966) concur that cardiac deceleration is a useful measure of the child's attention to visual and auditory information and that cardiac changes may reveal even more complicated psychological process For example, "work with infants suggests that, other things equal, a deceleration is most likely to occur in an infant when [he] confronts a moderate discrepancy from an existing schema, when the event surprises the infant" (Kagan, 1967) Kagan has also presented evidence for developmental changes in heart rate over the first two years of life (Kagan, personal communication) It should be noted that most psychophysiological studies of infants, even if aimed toward an analysis of developmental or environmental variables, also permit an examination of the stability of individual differences

Physiological Measures and Behavior The rapidly accelerating growth of interest in psychophysiological measures poses several problems for the psychology of infancy The prosaic but nontrivial problem remains of establishing common or translatable procedures from one man's laboratory to another's Assuming the accomplishment of that goal, there remains the major empirical problem of determining the nature of the interrelations

among several physiological measures and among physiological and behavioral measures A start has been made, for example, in Prechtl's (1968) work and in preliminary studies by Bridger, Burns, and Blank (1965) In measuring heart rate, judged movement, judged muscle tension, vocalization, and a combined behavioral measure ("excitation") under three conditions, Bridger et al found that heart rate correlated highly with judged excitation ($p = .79$) and that both heart rate and judged excitation showed high individual stability ($W = .91$ for heart rate and .69 for excitation) across conditions of stimulation Similar studies hold promise of providing an empirical matrix of interrelations among physiological and behavioral measures Beyond the empirical matrix, however, lies the need for theoretical proposals about the relevance and significance of physiological measures in understanding the infant We can say for physiological measures of the infant what will be said repeatedly and in different contexts through the present chapter—that we have only a rickety theoretical structure on which to display our growing sophistication of method and measure

From one point of view, the literature on physiological measures as well as the literature on behavioral measures can be seen to demonstrate a paradox of precision Most investigators start with interest in a process rather than a measure, in a problem rather than in a variable Early studies, whether of activity or perception or thought, are typically imprecise in two ways first, observations are not finely made and, second, several different *measures* may stand for the *process* studied (e.g., infantile distress may be indicated by vocalization, facial expression, and color change much as the beginnings of object permanence may be indicated by the child's response to hidden toys or peek-a-booing parents) The paradox lies in the fact that as precision of measurement increases there is a tendency for the relation between measure and process to become strained Sometimes the measure is held to *become* the process (e.g., heart rate deceleration as attention), sometimes the honing of the measure takes on such interest of its own that the connection with process fades almost altogether (e.g., the persistence of studies of general activity in infants) In a sense, as

we become more exact in our measures, we become less well connected with the problems that set us to search. The psychology of infancy has not been fully successful in refining its conceptual foundations to make optimal use of its refined measures of the response.

Behavioral Measures The larger part of the psychology of infancy depends on measures of overt behavior, the gestures and movements of the baby described topographically or instrumentally. The variety is in fact so great and so defining of the several ways in which human infancy has been understood that a taxonomy of responses seen in infants would be of little value. Attempted catalogues have been neither uniform nor obviously cumulative (see, for example, Blanton, 1917, Dennis, 1934, Peiper, 1963, Pratt, 1954, Richards and Irwin, 1934, Sherman and Sherman, 1925). Most behavioral measures have been of patterned activity—simple reflexes, movements of orientation toward aspects of the environment, avoidance responses, and emotional expression—but a good deal of continuing interest has been given over to the observation of *general activity* or *mass activity* in the young infant. A sketch of the history of general activity as a measure of the infant may serve to outline more general issues in the study of babies.

General Activity General bodily activity of the infant puzzled and interested early observers of infants for a number of reasons. General activity was puzzling in that, unlike the reflexes, it showed no obvious relation to particular events in the environment, “spontaneous” movements (Preyer, 1880) seem neither adaptive nor instrumental. Preyer posed the question of the relation between early general activity and later adaptive behavior and proposed something like a reinforcement mechanism to account for the selection and preservation of parts of the baby’s unpredictable activity. General activity was also of interest because, in spite of its unpredictability in detail, it showed obvious variation from time to time for a single child and substantial variation from one child to another. Early students of infants were especially interested in quieting, Moore (1896), for example, discussed the role of “inhibitory movements” in early intellectual and emotional development. However, as for most other

observers (e.g., inventors of tests for infant development), general activity was not of inordinate importance to Preyer, Moore, and their contemporaries, relatively gross characterizations of activity seemed sufficient.

Just before 1930, however, general activity became prominent as a measure of the infant. In substantial part the enlarged interest in activity and its precise measurement grew from a desire to make the study of infancy truly a part of the new natural science of psychology. Weiss (1929) opened a long series of studies at Ohio State University with a hopeful paper on the measurement of behavior. Then, too, something of a theoretical controversy fed the interest in infantile activity. Students of fetal behavior, and of reflex activity more generally, were divided on the issue of whether early behavior was diffuse and general, becoming more specific and reflexive or, on the contrary, whether early behavior was largely reflexive with the discussion of “mass activity” representing a failure to recognize component particular reflexes. The argument was taken up among students of infancy, with Dennis (e.g., 1932) defending the position that the baby’s behavior could most economically be represented as a collection of specific reflexes that became generalized through maturation and learning and with Irwin and Weiss maintaining that specific behaviors differentiated “from a primitive matrix of mass activity towards specialization” (Irwin and Weiss, 1930). On several occasions, Pratt (1934, 1936, 1937) reviewed these positions and attempted to compromise them, although his theoretical preference for the differentiation point of view showed through, and he wrote contemptuously of “fictionalized part activity” (Pratt, 1936). He spoke for a careful separation of stimulus-specificity and response-specificity and he drew the controversy to a close in a familiar way by defining the issues as largely empirical. Pratt proposed a grand array of observations with stimuli along one dimension and responses along the other. He felt that, in this way, over the years, psychologists might come to a “quantitative expression” of the relation between stimuli and responses (Pratt, 1937). Pratt’s position bypasses rather than solves most of the theoretical issues that turn on the definition of *stimulus*, *response*, and *process* but a sizable

proportion of research in infancy—again, particularly on the newborn child—can be seen as candidate for Pratt's matrix. But by the 1940s mass activity had lost its status as an article of controversy and had become largely just another measure in the search for empirical regularity. And, certainly, in the intervening decades, infantile activity has been the behavioral measure most often subjected to apparatus and to attempts of quantification. Three families of procedures have been used to make precise descriptions of activity—*human judgment*, *stabilimeters*, and *film*.

Human judgments of activity have appeared most often and in the largest variety. Sherman and Sherman (1925) were content with recording "jerkings"; Pratt, Nelson, and Sun (1930) attempted to describe the movement of body parts in the language of muscle mechanics and used "general activity" as a category only when the observer could not give a more precise description, categorical assessments of activity vary from a few rough divisions (e.g., Prechtl's [1968] *no movement*, *gross movement*) to many carefully described divisions (e.g., Birns' [1965] six-category system). Kestenberg (1965) used choreographic terms to describe "rhythms of movement." The variety is so great that the number of procedures for assessing activity by direct human observation is only slightly smaller than the number of studies in which activity is observed. Moreover, systems of description which are formally the same (e.g., categorical systems of four levels) have not been systematically compared. The deficiencies of direct human observation are well balanced, however, by the consideration that it does not require elaborate apparatus, that most systems can be easily taught, and that quite high reliability between observers can be obtained (Birns, 1965). But the major advantage of direct observation—and it is an advantage that permits serious metrical analysis—may lie in the possibility of making human judgment precise. After observing hundreds of infants of a particular age under a range of circumstances, the observer can build for himself a stable representation of the dimension of general activity. An experienced observer may then measure activity quite as sensitively as some instruments and, evaluated against the typical imprecision of stimulus control and theoretical analysis in

studies of infancy, his accuracy may be quite sufficient in many research applications.

Stabilimeter is a generic term for devices that more or less directly reduce the activity of the infant to a two-dimensional representation—time and position change. The instrument used by Weiss and his colleagues (Weiss, 1929) is typical, movements which the baby made as he lay on a pad were translated through tambours to a kymograph which displayed left-right and top-bottom movements. Instrumental variation is common. Wada (1922) rigged tambours to a crib at home to record diurnal variation in activity; Marquis (1931) used a platform with a fixed hinge at one end and a spring support at the other; Lipsitt and deLucia (1960) described a similar form that permitted, as well, the recording of some specific responses; Crowell, Yasaka, and Crowell, (1964) used photoelectric sensors and spring suspension to obtain both analogic and digital representations of activity. Variety of this sort makes stabilimetric recording liable to one of the limitations of direct observation—that comparison from one study to another is difficult. The instruments, however, provide a permanent record of observations made and permit fully objective scoring of the record. The latter advantage of stabilimetry is not always used. Although Irwin (*passim*) counted oscillations of recorded movement per unit time and Marquis (1931) counted half-minutes of recorded activity, some investigators (e.g., Lipsitt, 1963) have found that human observers, by inspection alone, can *judge* level of activity from stabilimetric records with sufficient accuracy.

Film, too, has a long history of use in recording the behavior of infants (e.g., Simons, 1925). Gesell and his colleagues were devoted to the use of filmed records (see, especially, *An Atlas of Infant Behavior*, 1934) and they developed objective procedures for scoring filmed records (Gesell, 1935a). Although more concerned with specific behavior patterns than with general activity, the Gesell group demonstrated the use of film in the study of individual differences in activity (Ames, 1942) and in the examination of phenomena such as laterality where a whole-body measure of activity will not serve (Ames, 1949). Other procedures for the use of film in recording infantile activity

have been reported by Bell (1960) and by Kessen, Hendry, and Leutzendorff (1961). Bell had human observers judge filmed records to assess level of activity (as well as three dozen other characteristics of the babies), Kessen et al proposed a measure of limb movement which permitted the study of patterns of movement among limbs and which could be calibrated from one laboratory to another. The advantage of precision available from filmed records has been offset somewhat by two disadvantages—relatively long processing time and the lack of fast and accurate techniques for scoring film. The first difficulty will be reduced, if not eliminated, by the introduction of television monitoring and videotape recording to infancy studies (Engle and Hansel, 1961, Haith, 1969), the second has been mitigated by the description of efficient procedures for reducing filmed and videotaped data (Haith, 1966, 1969).

Despite its origin in controversy and its appeal to investigators caught up in a search for precise measures, infantile activity has survived as a prominent indicator of the baby's behavior because it is relatively sensitive to environmental variation and because it holds promise as a revealing mark of stable differences among babies. Activity has been reported to vary systematically with time since feeding (Irwin, 1932), level of ambient illumination (Irwin and Weiss, 1934, Irwin, 1941), swaddling (Crowell et al, 1964), nonnutritive sucking (Kessen and Leutzendorff, 1963), procedures designed to produce temporal conditioning (Marquis, 1941), psychophysiological measures of arousal (Bridger, Burns, and Blank, 1965, Gordon and Bell, 1961), repeated presentation of stimulation (Bridger, 1961, Burns, 1965), the complexity contained in a visual display (Haith, Kessen, and Collins, 1968), and the list can be extended.

Activity level of infants has been proposed as an important dimension of human variation by a number of investigators. Mittelman (1955) has connected variations in motor patterns to symptom formation. Stambak (1956, Lézine and Stambak, 1959) has reported that variations in motor tonicity can be linked to variations in locomotor development, feeding responses, and patterns of exploration. Kestenberg (1965) has proposed a longitudinal study of the correlates of con-

genital patterns of rhythm in movement. Fries (Fries and Lewi, 1938, Fries and Woolf, 1954) has long maintained the theoretical significance in understanding later personality of a "Congenital Activity Type." Recognizing that early variations in activity are not related in a simple fashion to adult personality, Fries has asserted that Congenital Activity Type influences the child's relation to others, patterns of psychological defense, and susceptibility to pathology. Thomas, Chess, Birch, and Hertzog (1963) have described, among other measures, individual stability in activity level over the first two years of life. Schaffer (1966) presented evidence that infants of low activity level respond to social deprivation less well than their high-activity agemates. Even more provocative are reports of significant correlations between *fetal* activity reported by mothers and developmental test scores during the first eight months of life (Richards, and Newbery, 1938, Walters, 1965).

In general, the weight of assertion about the importance of general activity in determining future development seems more than the available data can bear. Suggestive findings by several investigators of *short-term* regularities in activity level are hardly sufficient to justify the claims made for general activity as a central dimension of personality. Kagan (1968) has, in another connection, stated the general form of a question that must be put to proposals about the relation of early activity to later behavior. No one is seriously interested in variation in early activity as a predictive indicator of variation in activity among adults or even among older children. Rather, each theorist proposes a (different) set of transformations such that early differences in activity level show up in later differences in patterns of tension discharge, symptom formation, or strategies of problem-solving. The conceptual links between early behavior and its later manifestations are not always clearly shown and the demonstrated empirical support for the transformations that have been proposed is slight. Kagan lodged the issue in the contrast between genotypic and phenotypic characterizations of the infant's behavior, the phenotypic expression of general activity is seen to be of interest only as it indicates some psychological process or genotype.

Here, too, the study of infantile activity can stand as typical for other behavioral measures of the baby. Only short-term stable individual variation has been demonstrated, theoretical statements about the psychological process underlying variation in activity have been vague or careless, and demonstrations of continuity in process—genotype continuity—have been rare indeed.

Activity as Representative of Behavioral Measures of Infants General activity has been widely used in infancy research, it has attracted more apparatus than most behavioral measures, and it has been assigned great weight in attempts to understand early individual differences. For these reasons, general activity may serve to represent, *primus inter pares*, other behavioral measures. The following problems, which we have seen illustrated for activity, must be engaged in the use of other behavioral measures.

Measurement There are three questions to ask about measurement. First, does the measure reliably indicate changes in the same baby across varying conditions? An affirmative answer can be given at several levels of precision, but, at a minimum, the question requires only that a *change* in the value of the observed variable be reliably detectable. Limited by the danger of regression effects and by slight generalizability, change measures that are reliable within subjects are common in infancy research. Second, does the measure reliably indicate differences between babies? Here at least an ordinal scaling must be possible for the measure under observation. Much of the attention given to the assessment of general activity—and, again, other behavioral measures follow the example—has been devoted to finding an affirmative answer. Finally, can the measure be applied uniformly from one observational setting or laboratory to another? A positive answer to this question would permit us, for example, to determine whether the most active baby observed in Akron was more active than the most active baby observed in Sacramento. Although filmed and videotaped records of infants offer some promise that fully generalizable measures will be found, it is a fair reading of the literature to say that few, *if any*, standard and precise metrics of infant behavior have ever been developed and applied widely. Of course, serious and informative studies of babies do

not require an affirmative answer to our third question, but the lack of a shared system of measurement limits the cumulative impact of infancy studies.

Observation in Context It is often said of research that all empirical observations represent an interaction of many variables, and consideration of context—the setting for observation in all its complexity—is of prime importance in infancy studies. The paucity of standard measures, the absence of unifying conceptual schemes, and the fast rate of change of behavior in the first 18 months of life all impose a need to recognize and to describe, even if one cannot precisely measure, the instrumental and procedural characteristics that distinguish one study from another. Until a rough taxonomy of research procedures, settings, and apparatus is established, interpretations linking one study with another will be somewhat shaky. Bell (1963) has analyzed, for the limited case of the newborn infant, the disconcerting range of factors in the setting or in the baby that must be understood in order properly to interpret observations which are apparently straightforward. Even for general activity, the behavior of newborn infants most often observed, general principles of great scope cannot be stated. At least part of the disability can be charged to the fact that psychologists of infancy, particularly the experimental psychologists of infancy, have developed neither standard procedures for observing the baby nor translation rules for relating the work of one laboratory to the work of another.

From Observation to Interpretation An examination of the use of behavioral measures in infancy studies leads inescapably to the conclusion that *response*, like *stimulus*, is defined by hunch, prejudice, and theory as well as by replicable observation. However tough-minded and empirical an investigator aims to be, he shifts easily from a description of observed behavior to a discussion of assumed process. Explanation is, of course, both a normal part of any systematic study and the conceptual basis of response definition in the infant. It is worth noting here chiefly because of the strongly descriptive character of much research in infancy. Hall's program has been followed—"only the laborious comparison of many special and painstaking observations can yield results of value" (Hall, 1891)—but

a psychology of infancy is far more than *look-see*, however sophisticated. Once again, the case of general activity serves in its illustrative role. Variation in activity has been explained in so many different ways (see Gordon and Bell, 1961, for a brief summary) that the weak connections between observation and interpretation are fully exposed.

Mental Structures of the Infant

In addition to Hall's empiricistic successors, who took variance wherever they found it, several general theoretical positions have influenced the conduct of research on babies. Though none was developed as a theory of early behavior in the first instance, propositions about babies can be drawn from them all. More or less coherent conceptual treatments of the infant are contained in or implied by the work of Freud and his followers (Freud, 1905, Rapaport, 1951, Spitz, 1965, to name a few), Koffka (1924), Gesell (especially 1925 and Gesell, Thompson, and Amatuda, 1934), Piaget, (1927, 1936, 1937, 1945), child psychologists and psychiatrists influenced by the ethological movement (e.g., Bowlby, 1958, 1960), and the investigators in several traditions who see the infant chiefly as a learner (Watson, 1928, Stevenson, 1962, Bijou and Baer, 1961). Several chapters of this book contain resums of major theoretical positions in child psychology and the relevance of the theories for infancy can be seen there. Moreover, some comparisons among theories have been made over the past decade (Baldwin, 1967, Kessen, 1965, Maer, 1965, Wolff, 1960). Therefore no review of psychological theories of infancy will be undertaken here.

However, unlike some areas of child psychology, infancy has attracted the attention of almost every theory of the child, thus several comments about theories of the child—the mental structures ascribed to infants—may be in order. It was suggested earlier that there is not a generally accepted body of *facts* which different theories can aim to encompass, rather, each conceptual point of view brings with it, explicitly or implicitly, rules for determining what constitutes a fact about the baby—that is, what constitutes a relevant arrangement of the environment and a relevant observation of the child for the particular theory under consideration. The

differences that separate theories of infancy are fundamental. They are not different ways of talking about the child, they are different ways of knowing what the child is. Decisions about the elemental nature of the baby interlock with the selection of problems for study, assumptions about process and the selection of typical problems, in turn, influence procedures for obtaining information and the ways the “facts” are finally reported. It is neither surprising nor inconsequential that theorists of the infant cluster with men of like mind, investigators separated in time and space are linked by their adherence to a particular way of seeing children.

Just as theories do not meet on the same domain of observations, neither do they maintain nonoverlapping, independent territories. Occasionally, varying conceptual attitudes are brought to bear on what seems to be roughly the same phenomenon. Perhaps the clearest example of this direct encounter is the diversity of treatment, theoretical and empirical, given social development in the first year of the (see Maccoby, Chapter 21 of this book). Ainsworth (1963), Gewirtz (1961), and Spitz (1965) manage to make disconcertingly different statements about the baby and his first social attachments. A disagreement about the nature of the infant does not necessarily imply the existence of a contradiction, the incompatibility of varying explanations, or the existence of a “correct” alternative among the candidates. We are quite without systematic ways of making evaluative comparisons among theories of the baby. Rather, in the pages ahead, as we discuss procedures and problems, there will emerge several loosely connected sets of techniques, definitions, and conceptual propositions which represent the major points of view that exist in the field of infancy.

SOURCES OF INFORMATION ABOUT INFANTS

Observations of infants have been made because the researcher was fascinated by his own children, because the regularities of early development called almost aloud for precise and numerical description, because a problem of interest to the investigator in another domain (e.g., language, embryological differentiation, perception of space) seemed amen-

able to clarification by observation of infants and, less happily, because certain observations made on animals or adults had not yet been made on infants. The diversity of approaches to the study of infants and the remarkable relation between approach and outcome can be fairly represented if we consider *baby biographies*, *normative studies of development*, *longitudinal studies of early personality*, *laboratory studies*, and *other systematic procedures*. The categories are neither exhaustive nor exclusive but they permit the sorting of most observations on babies.

Baby Biographies

Many studies of the child depend on reports of parents but, because it is in the Western mode to keep the child at home during the first years of life, the study of infancy is unusually indebted to the relatively small number of parents who have watched and recorded the behavior of their children and then gone on to order and organize their observations in a way that permits sharing them with colleagues. Tiedemann (1787, translated by Muirchison and Lange, 1927), who is often afforded the ritual honor of being the first baby biographer, apparently drew his inspiration from the self-revealing work of Rousseau and from the contemporary interest in developmental physiology. Almost 100 years later, again provoked by the more general biological problem of development posed by Darwin, the era of the baby biography began, grandly in the work of Preyer (1881), more modestly in notes about their children by eminent men like Taine (1877), Darwin (1877), and Champneys (1881). Dennis searched the literature for baby biographies in 1936 and found evidence of narrative accounts of infancy by 48 authors. When infancy studies became more rigidly scientific, enthusiasm for narrative parental accounts diminished, nonetheless, profoundly important examples of the form have appeared since in the work of Piaget (1936, 1937, 1945), in Valentine's (1930) study of fear, and in the observations of students of early language acquisition (e.g., Lewis, 1951, Leopold, 1939, 1947, 1949).

There is, of course, no agreed-on procedure for making a baby biography, they share the characteristic of being observational rec-

ords on one or a few children made by parents of the observed child and continuing over several months (in some cases, over several years) of the child's life. Within so lightly defined a category there are studies of precise and limited intentions (e.g., Fairbanks, 1942, studied changes in the pitch of hunger wails over the first nine months of his son's life) as well as major attempts to understand the full scope of the baby's development. Biographical studies, of whatever dimension, suffer from the possibility of grossly contaminated observation by a loving parent who is typically also a professional psychologist with a point to make. The biographies also do not permit a systematic parametric analysis of variables influencing the child, a characteristic which may help to explain why no one has made the careful comparative study that the rich biographical literature demands. The limited summary of the biographies by Dennis and Dennis (1937) is encouraging, nonetheless, in demonstrating the regularity, across different accounts, of the timing of developmental changes.

Careful study of the biographies is justified because, even if one stipulates the bias of the parent-observer, he has a far better understanding of the baby's environment than is approached by the usual study of many children, whether normative or experimental. More than that, the biographer can organize his observation and speculations around the elemental fact that he is seeing a single coherent *person*, his descriptive task and his theory, if you like, are defined by the continuing and connected existence of another human being. More formal approaches to the psychology of infancy can offer neither conceptual coherence nor procedural elegance sufficient to match the biographer's *coherence of person*.

For all the technical arguments that can be made about the reliability and comparability of biographical data, the parental studies of early life have two remarkable properties that make them a major source of interest to observers of babies. First, biographies contain an enormous amount of information. Taken together, they comprise the most general and inclusive source of information about the child in the first two years of life that is available to us. The student of children who wishes to see the baby portrayed in broad

and sometimes hesitant strokes, but fully human and fully persuasive, will wisely read Piever (1881), Moore, (1896), Shinn (1900), and Piaget (especially 1936) Mrs Moore wanted to describe all of her baby's mind, even though she recognized the necessity of abstraction and weakly supported generalization, Table 1, which shows some of her observations on recognition and inference, will illustrate the peculiarly important contribution of the baby biographer.

The empirical richness of the biographies is as remarkable as their selective character. To be sure, some accounts have been explicitly narrow in scope—most obviously those concerned with language—but all biographies, even those that aim for simple observational generality, represent their time and their authors. Darwin (1877) and Mrs

Hall (1895–1896) concentrated on the development of emotion or, better, the development of sentiment. Teidemann (1787) and Piever (1881) wrote out of current psychology about sensation, volition, and the role of experience. Baldwin (1895), Mrs Moore (1896), and Piaget (*passim*) saw the child as young philosopher and logician. The Kelloggs (1933), in their valuable study of early development in chimpanzee and baby, wanted to know how much a common environment could reduce species differences. The selectivity of attitude and the variety of conclusions shown in the biographies is not so much a measure of the inelegance of the method but rather of the fact that early human development is so many-sided that there exist many ways to make useful analytic reduction. Even so, there are communalities enough in the

Table 1 K C Moore's Summary (1896) of the Development and Relation of Recognition, Inference and Reconstruction in Her Son

Simple Recognition Based on Experience	Recognition Connected with Expectation	Con- clusions upon Analogous Items of Experience	Reconstruction	
			Either a Simple Reorganization of Experience	Or a Reorganization involving an In- ference
5th week He recognized the human face	21st week He recognized hands extended to him and expected to be taken up	24th week He tried to take the hand of his own reflection in the mirror	81st week He threw his baby doll on the floor and ran into another room calling "Bye, baby!"	66th He found on the floor a bit of black wool about the size of a fly which he at once called a fly. He picked it up, carried it to the window and stuck it on the screen. Then he pointed to it, exclaiming, "fly! fly!" a number of times
7th week The sounds of the voice	22nd week The spoon, and prepared to receive water	25th Seeing a visitor wearing a hat he evinced delight, when she went out and did not take him he was distressed	Then exclaiming, "Poo! baby cry!" he ran back and picked it up. He laid the doll on the bed springs and worked them up and down, giving the doll a ride as his grandmother rode him	
9th week He recognized the breast when he saw it, and the face of his mother	23rd His mother's hat, expecting to be taken out when she wore it	59th Seeing a cow for the first time the child called her a bird		
12th week His own hand	27th He recognized a tune, and expected it if he saw the movements which accompanied the song	64th A caterpillar he called a fly	93d Upon going into the bathroom he asked for a large empty bottle which was often given him to play with. Having received it he said, "Mamma, neck"	
16th His thumb, the nipple	35th Repeatedly threw his spoon on the floor and looked after it, sometimes he held out his hand as if to receive something, seeming to expect it to come to him	83d week In the afternoon the child walked in the station with his parents and rode in the street car. In the evening he and his mother went back to the station alone. When the		
17th He recognized his ball at a distance of some feet				
18th Footsteps on the stairs				
24th week He recognized his grandfather, whom he had not seen for two weeks.

	trouble in remembering where in any part of the room she sat		doors "See the books in the window!"	now there, as if giving the same pin to each in turn	after the child in telling about his grandfather always represented him as picking grapes
			98th In the forenoon he saw a neighbor sweeping snow In the afternoon when questioned as to her whereabouts he replied that she was sweeping the snow (he had not in the meantime seen her)		
			100th Seeing his mother tacking down an oil cloth on the kitchen floor he exclaimed that the kitchen was broken (he had seen things mended with hammer and tacks)		
			101st The corner of his napkin bent up against his face, and this he attributed to the wind which blew under his cape and raised it in a similar manner		
			103d He broke the petiole from the blade of a leaf and asked his mother to mend it She replied that she could not do so He sat as if thinking for a few moments, then looked up and said, "Mamma mend(ed) the sofa, mamma mend(ed) the rabbit"		

records—for example, in records of emotional expression and of language—to justify more careful comparative study of them

The biographies have the defects of their virtues: idiosyncratic selection makes comparison difficult, variation in observational procedure limits parametric analysis of variables, and the coherence of person that makes them convincing human documents often frustrates the student in search of an objective account. But, despite their weaknesses, the biographies are essential in our studies of language, emotional expression, problem solving, representation, and imitation in infants and they remain invaluable sources of observations and of leads toward better controlled observations on other matters of interest to the psychologist of infancy, particularly in the period between the newborn's hospital stay and the child's entrance into nursery school.

Normative Studies of Behavioral Development

The second major source of information about infants lies in large-scale studies of developmental regularities in behavior, the normative investigations that have produced, among their other achievements, the infant test. Bayley (in this book) deals with empirical and procedural issues in the measurement of development across the growth span, the account here will therefore review briefly only normative studies of mental development in infancy. Binet (1905) included in his first intelligence scale a few items appropriate for the infant (e.g., visual following of a lighted match, prehension of an object seen, the execution of simple commands) but his later revision provided only for assessing the behavior of children at least 3 years old. Kuhlman (1912) began modifying the Binet scale for younger children and published items appropriate for children from 3 to 24 months of age in 1922. Simon (1916) proposed a detailed "questionnaire" to guide the observation of children between birth and 2 years and parts of his proposal were translated by Reymert in 1920. With the publication of Gesell's (1925) first scale of infant behavior, procedures for assessing early development came thick and fast. Developmental schedules, rarely altogether independent of one another and often leaning heavily on Gesell,

were described by Hallowell (1928), Linfert and Hieholzer (1928), Jones (1926), Stutsman (1931), Shirley (1931, 1933), Buhler and Hetzer (1932, 1935), and by Bayley (1933, 1936). Although the pace slowed after the mid-1930s, several new scales of infant development (as well as revisions of earlier procedures) have appeared, for example, the tests of Cattell (1940), Brunet and Lézine (1951), Griffiths (1954), and, in preliminary form, Uzgiris and Hunt (1964). For the narrower range of newborn behavior, early catalogues like Blanton's (1917) have been succeeded by standardized tests like Graham's (1956, Graham, Matarazzo, and Caldwell, 1956, Rosenblith, 1961, Rosenblith and Lipsitt, 1959).

Prodigious effort has been expended in the development, standardization, and application of normative schedules for infant behavior. Buhler and her colleagues made 'round-the-clock observations of children at intervals of 1 month in order to develop time-representative items. Boyd and Shirley made 1370 home visits and carried out 1944 behavioral examinations in the 2 years of their longitudinal study (Shirley, 1931). Bayley (1965) organized the testing of over 1400 infants under 15 months. Gesell, during the 25 years he studied infants systematically at the Yale Clinic of Child Development, applied his developmental schedule to thousands of normal and pathological babies, accumulating along the way miles of filmed records. The list could be extended to include scores of research applications of developmental scales for infants. From these studies has come the largest body of *descriptive* data available in the literature of infancy. However, in addition to variation among the tests themselves in content, standardization procedures have not been of uniform high quality (compare, for example, Gesell et al., 1934, with Griffiths', 1954, sophisticated standardization), and testing procedures, even for the same tests, have varied. Nonetheless, uniformities in the ways the tests were constructed (Hindley, 1962) have exerted regularizing force on most of the scales. Items assessing development of locomotion are often used as measures of speech development—though here the differences among tests are substantial (McCarthy, 1954). Characteristically present also are items assessing sensory and percep-

Table 2 Items Drawn from Four Infant Tests Which Are Considered Appropriate for Six-Month-Old and One Year-Old Infants

Gesell and Amatruda (1941)	Bayley (1933a)	Cattell (1940)	Griffiths (1954)
(Key age, 28 weeks)		(Key age, 6 months)	(Key age, 6 months)
Lifts head	5 8 mo Exploitive paper play Present	Secures cube on sight	Plays with own toes
Sits erect momentarily	a piece of paper to child so he may grasp edge of it	When child is sitting in upright position before table a one-inch cube is placed within easy reach	Sits with slight support
Radial palmar grasp of cube			Anticipatory movements when about to be lifted
Whole hand rakes pellet	5 8 mo Accepts second cube When child is holding one cube, place a second in easy reach	Lifts cup Place straight-sided aluminum cup upside down within easy reach of child as he is sitting at table	Manipulates bell
Holds two cubes more than momentarily			Makes 4+ different sounds
Retains bell	5 9 mo Vocalizes pleasure	Fingers reflection in mirror While child is in sitting position, a framed mirror is held before him in such a manner that he can see his reflection but not that of his mother or other persons	Secures dangling ring
Vocalizes m-m m and polysyllabic vowel sounds	5 9 mo Vocalizes displeasure		Hands explore table surface
Takes solid food well	6 0 mo Reaches persistently Place cube just far enough away from child so he cannot reach it Credit if he reaches, persistently		Holds two cubes
Brings feet to mouth			
Pats mirror image	6 1 mo Turns head after spoon Hold spoon so that it protrudes over edge of table by child's side and when he is interested, suddenly drop it to floor	Reaches unilaterally Child sits with shoulders square to front and both hands an equal distance from examiner A two-to-three inch door key or peg is presented in perpendicular position	
	6 1 mo Mirror image approach Hold mirror before child, bringing it close enough so that he may reach it easily	Reaches persistently One-inch cube is placed on table just out of child's reach Credit if child either reaches several times.	
	6 2 mo Picks up cube deftly	Approaches second cube Child is presented with one cube and as soon as he has taken it a second is held before him in such a position as to favor his grasping,	
	6 3 mo Says several syllables		

Table 2 Items Drawn from Four Infant Tests Which Are Considered Appropriate for Six Month-Old and One-Year-Old Infants

Gesell and Amatruda (1941)	Bayley (1933a)	Cattell (1940)	Griffiths (1954)
(Key age, 52 weeks)		but is not actually placed in his hand (Key age, 12 months)	(Key age, 12 months)
Walks with one hand held	11 5 mo Inhibits on command When child puts an object in mouth or on some other pretext, say "no, no "	Beats two spoons to- gether Two spoons are taken, one in each hand, and beaten gently to- gether while child watches, then they are presented to child, one in each hand	Side steps around in- side cot or play pen holding rails
Tries to build tower of cubes, fairly	Credit if he inhibits		Obeys simple request, "Give me cup," etc
Dangles ring by string	11 6 mo Repeats performance laughed at	Places cube in cup Aluminum cup and one-inch cube are placed before child and he is asked to put "block" in cup If no response, plac- ing cube in cup is demonstrated and request repeated	Plays "pat-a cake" (claps hands)
Tries to insert pellet in bottle			Reacts to music vocally
Two words besides "mama" and "dada "		Marks with pencil Piece of paper and pencil are placed before child with request, "—write "	Babbles monologue when alone
Gives toy on request		If no response writing is demon- strated and request repeated Credit if child makes any marks on paper	Says three clear words
Cooperates in dressing	11 6 mo Strikes doll Place small rubber whistle doll on table Hit it smartly to produce whistle, encourage child to do the same Credit if he imitates the hitting motion		Interested in motor- car
Releases ball towards adult (56 weeks)	11 7 mo Imitates words Say several words, as mama, dada, baby, etc , and credit attempts to imitate	Rattles spoon in cup Aluminum cup is placed before child and spoon is moved back and forth in it, hitting edges, then spoon is placed beside cup with handle toward child	Uses pencil on paper a little
	12 1 mo Spoon imita- tion Rattle spoon in cup with stirring motion Credit if child succeeds in making a noise in cup by a similar motion with spoon	Speaking vocabulary —two words "Ma-ma" and "da- da" are not credited.	Manipulates box, lid, and cubes
	12 2 mo Holds cup to drink Hand cup to child saying, "Take a drink "	Hits doll Rubber doll with whistle is put face up on table	

Table 2 Items Drawn from Four Infant Tests Which Are Considered Appropriate for Six-Month-Old and One-Year-Old Infants

Gesell and Amatruda (1941)	Bayley (1933a)	Cattell (1940)	Griffiths (1954)
	holds it adaptively to drink	before child, and hit gently with open hand several times	
	12 6 mo Adjusts round block Three- hole (Gesell) form board is laid on table with round hole at child's right Give round block to him with no directions Credit if child puts block in round hole	Credit if child makes a definite at- tempt to hit doll	

tual functioning, social responsiveness, and memory or learning Table 2 illustrates the similarities and differences among infant tests by listing the items deemed appropriate for the 6-month-old and the 1-year-old from the work of Bayley, Cattell, Gesell, and Griffiths

Normative studies of early development have had two aims to describe the regular change in behavior with age for all children—the stability of the species—and to describe variations among babies that might permit reliable diagnosis and prediction—the stability of the person With rare exception, the inventors of developmental schedules have been primarily concerned with the second, the *diagnostic* issue Their search has been for ways to foresee the later development of babies for practical (e g, in justification of adoptive placement) as well as for theoretical reasons But the literature supports the conclusion that, however well we may know the timing and sequence of many responses in

the human infant as member of a species, we have not been able to devise procedures sufficient to the diagnostic and predictive task Intratest and interobserver reliabilities are generally high (see, for example, Griffiths, 1954, Cattell, 1960, Werner and Bayley, 1966) Short-term test-retest reliabilities are also positive and sometimes high (Bayley, 1933b), although the summary of several studies in Table 3 shows that test-retest correlations rarely exceed .50 during the first three years of life Several of the tests seem to be accounting for common variance Pease, Rosauer, and Wolins (1961) in a comparative study of the Bayley, the Gesell, and the Cattell, and Caldwell and Drachman (1964) in a comparison of the Cattell, the Griffiths, and a modified Gesell have shown that, across a narrow age range, the several scales intercorrelate highly But the capacity of infant development scales to forecast later measures of intelligence is slight Bayley (1933, 1949),

Table 3 Intercorrelations of Averaged Test Scores within the First Three Years of Life

	4, 5, 6 Months	7, 8, 9 Months	10, 11, 12 Months	13, 14, 15 Months	18, 21, 24 Months	27, 30, 36 Months
1, 2, 3 m	.57	.42	.28	.10	-.04	-.09
4, 5, 6 m.		.72	.52	.50	.23	.10
7, 8, 9 m.			.81	.67	.39	.22
10, 11, 12 m.				.81	.60	.45
13, 14, 15 m.					.70	.54
18, 21, 24 m						.80

Hindley's (1962) casting of Bayley's (1933b) longitudinal data

Anderson (1939), Cattell (1940), and Wittenborn (1957), among others, have demonstrated that the correlation between developmental measures in the first 18 months of life and tested intelligence scores between 5 and 18 years is effectively zero. Anderson's study may be taken as representative. Using three of the standard tests and some items of his own, he found that intelligence scores at 5 years correlated with 24-month scores at .45, with 18-month scores at .23, with 12-month scores at .06, with 9-month scores at .00, with 6-month scores at -.06, and with 3-month scores at .01. Whatever the reasons for the findings of low predictive value—general lack of stabilization in infantile functions, failure to sample "appropriate" behaviors, or the differentially greater impact of early experience on intelligence—Anderson's summary remains appropriate.

Infant tests, as at present constituted, measure very little, if at all, the function that is called "intelligence" at later ages. It is unfortunate that workers in the pre-school period have used age-progression as virtually the only criterion for validating their tests (1940).

Not all investigators are convinced that accurate prediction of later intelligence cannot be made from early observations of babies. Illingworth (1961), Escalona and Moriarty (1961), Holden and Solomons (1962), Donofrio (1965), and Knobloch and Pasamanick (1959, 1962, 1963) have all argued for the clinical utility of early developmental testing. Each of these studies, however, involves either a sample biased toward low scores in a way that makes statistical interpretation difficult or it adds to developmental test scores another sort of observation such as "clinical appraisal based on test performance" (Escalona and Moriarty, 1961) or "a diagnosis of neurological status" (Knobloch and Pasamanick, 1959). The arguments presented suggest that characteristics of the test situation and aspects of the baby's behavior beyond his measurable performance on test items must be taken into account. Certainly it is the case that, over the years, pediatricians and neurologists have developed techniques for the assessment of the infant's neurological condition that may amplify and correct the findings of developmen-

tal tests. Although rarely cast in the strict psychometric form of infant tests, the behavioral observations of André-Thomas and his colleagues (e.g., Saint-Anne Daigassies, 1962) and of Peiper (1963) are essential to an understanding of the infant, particularly of the newborn. Parmelee (1962) has published a summary of current European neurological studies and Saint-Anne Daigassies (in Falkner, 1966) has summarized her observations on premature and term babies. Fiorentino (1963) has described a large number of reflex tests of central nervous system development in the 1½ years of life. A far simpler procedure for the evaluation of the newborn infant proposed by Apgar (1953, and James, 1962) has been used by students of infancy in assessing the sequelae of prematurity and perinatal anoxia.

On balance, the obvious contribution of the normative studies has been to describe in some detail the expected course of development in the first two years of white, Western, family-reared children. They also provide a procedure for assessing short-term developmental effects such as the relation of fetal activity to early development (Richards and Newberry, 1938; Bernard, 1964; Walters, 1965) and of the action of contemporaneous environmental change on behavior—for example, the effect of separation. Test performance has been used to measure cross-cultural and subcultural variation (e.g., Knobloch and Pasamanick, 1953; Geber and Dean, 1957; Vincent and Hugon, 1962), to measure the effect of institutionalization (Lipton and Provence, 1963), and to find the influence of sex, birth order, and characteristics of parents (Bayley and Schaefer, 1964; Bayley, 1965) as well as in extensive studies of prematurity and early pathology.

The search for normative measures with predictive power goes on. One tactic is represented by Uzguis and Hunt, who have begun their search for test items on theoretical rather than empirical grounds, drawing largely from the work of Piaget (1936, 1937, 1945). Another, older procedure seeks items in present tests that are differentially sensitive to later performance. Anderson (1939) and Maurer (1946) made early use of the procedure, Werner and Bayley (1966) have recently shown that *rehabilities* are higher for test items that deal with independent move-

ments of the baby's body and activity directed toward objects than they are for responses which involve a social partner. Cameron, Levson, and Bayley (1967) have recently followed up weak suggestions in the literature (e.g., Abt, Adler, and Bartelme, 1929, Catalano and McCarthy, 1954, Karelitz, Fischelli, Costa, Karelitz, and Rosenfeld, 1964) that vocalization and early speech may be more intimately related to mature intelligence than other aspects of early infant behavior. Still, Stott and Ball (1965), after a close quantitative analysis of several currently used infant tests, conclude that there is "a great lack of consistency among and within the scales in terms of factor content and meaning, thus pointing up the need for more consistent and adequate test scales."

Studies of Early Variation in Personality

When Mary Shirley reported her observations on personality development in the first two years of life, she commented "there are no studies of personality at the infant level with which the results of this study can be checked and its theoretical interpretations compared" (Shirley, 1933). As she wrote, several studies that aimed to follow children from birth until maturity were being started and, over the years, several more have been initiated. But, for all the keen and apparently increasing interest in the longitudinal study of behavior (Bell, 1953, Anderson, 1954, Kessen, 1960, Schaefer, 1965), the public literature on connections between baby's behavior in the first years of life and his personality during adolescence or adulthood is very small. Stone and Onqué (1959), in their survey of follow-up studies of personality, found only a scattering of reports that involved very young children. Among them were Washburn's study of laughing and smiling in the first year (1929) and of child-care procedures in the first two years (Washburn and Putnam, 1933), a report on MacFarlane's (1938) study of guidance, studies on a very small number of children by the Gesell group (Gesell and Ames, 1937, Ames, 1944) and their successors at Yale's Child Study Center (Coleman, Kirs, and Provence, 1953, Wolf, 1953), a study of Shirley's babies after 15 years (Neilon, 1948), and some parts of Bayley's unique work. Reports on work completed or planned linking infant behavior to later personality have since

been presented by Meili (1957), Escalona and Heider (1959), Skard, Inhelder, Noeltig, Murphy, and Thomas (summarized in David and Brengleman, 1960), Kagan and Moss (1962), Thomas, Chess, Buch, Hertzog and Kohn (1963), and Schaefer and Bayley (1963).

The variability in instrument and procedure that characterizes longitudinal studies of motor and mental development is, not surprisingly, of a low order when compared with studies of early personality. We have some sense of what adult intelligence is and how to assess it, we have only a beginning notion of the dimensions of adult personality. Studies of infantile personality share an interest in some large categories (e.g., activity, impulsivity, and social response, particularly dependency and aggression) but there appear to be *no two studies* in the literature where the same instruments and the same procedure for personality assessment were used. Table 4 lists the categories for describing early behavior used by Gesell and Ames (1937), Bayley (Schaefer and Bayley, 1965), Kagan and Moss (1962), and Thomas et al. (1963). The rarity and value of data connecting infantile with adult characteristics make the diversity of technique insignificant, but there exists a clear need for integration and organization of information from the several studies. In general, short-term stability of observed characteristics has been established. Schaefer and Bayley compare four age groupings between 10 months and 36 months, Kagan and Moss compare years 1, 2, and 3 with years 4, 5, and 6, Thomas et al. present interview data drawn from six periods in the first two years—all concur in finding significant stability in observations of personality traits. But, in the few studies that report extensive data from infancy to adolescence or early adulthood, there is the familiar decay in the strength of relation from age period to age period. The work of Kagan and Moss and of Schaefer and Bayley can illustrate the conclusion. Kagan and Moss (1962) report some 174 correlations of characteristics of children in the first 3 years of life with characteristics of adults, of these, only 4 are statistically stable. Schaefer and Bayley (1963) report 784 correlations of characteristics observed between 10 months and 3 years with characteristics of adolescence, of these, 44 are statistically stable. In

Table 4 Examples of Categories Used to Describe Dimensions of Early Personality in Four Studies

Gesell and Ames (1937)	Kagan and Moss (1962)	Thomas et al (1963)	Schaefer and Bayley 1965)
Energy output	Passive and dependent behavior	Activity level	Responsive to persons
Motor behavior	Aggression	Rhythmicity	Rapid
Self-dependence	Achievement	Approach-withdrawal	Active
Social responsiveness	Interaction with opposite sex	Adaptability	Not shy
Family attachment	Physical harm anxiety	Intensity of reaction	Happy
Communicativeness	Social interaction	Threshold of responsiveness	Positive behavior
Adaptivity	Compulsivity	Quality of mood	Calm
Exploration of environment	Hyperkinesis	Attention span and persistence	
Humor sense			
Emotional maladjustment			
Emotional expressiveness			
Reaction to success			
Reaction to restriction			
Readiness of smiling			
Readiness of crying			

the latter case, a disproportionate number of high correlations were reported for the girls in the sample and in the pattern that relates rapidity and activity in early life with adolescent characteristics of independence, boldness, irritability and defiance. The Schaefer and Bayley work also contains the provoking suggestion, in part confirmed by Kagan and Moss, that characteristics of mothers in the first three years of life, for boys at any rate, may be a better indicator of adolescent behavior than the child's own earlier behavior. It should be noted, however, as Bloom (1964) has noted for other human characteristics, that there is a tendency for personal stability to increase markedly during the second three years.

Strangely, some of the apparently most successful long-term predictions have been made in the *gross* categories of individuality used by Gesell and Ames (1937) and by Escalona and Heider (1959). Even more dramatic is Neilson's (1948) study in which she made a clinical assessment of 16 of Shirley's original 25 children when they became 17 years old. She gave clinical sketches of the children at 17 to some 15 judges together with clinical sketches of the children made at 2 years of age. The task of the judges was to match the two sets of data. Matches were made at statistically stable levels and the pattern of concurrence is strikingly close. As in the case of the baby biographies, we may be able to construct some sense of the

person but be unable to dissect and analyze our judgments into diagnostic and predictably effective categories. In spite of slight evidence of stability, our inability to make predictions of later personality from observations in the first three years of life is so much against good sense and common observation, to say nothing of the implication of *all* developmental theories, that the pursuit of predictively effective categories of early behavior will surely continue unabated.

Laboratory Studies

The line between sensitive observation in natural settings and systematic laboratory studies is not easy to draw. Defined loosely, laboratory studies are distinguished by attempts to control stimuli and to vary them systematically, by close attention to the reliability of response measures, and by the use of comparable observations on a fair number of infants. The use of strict experimental procedures, with random assignment of subjects to differing treatments, has not been a distinguishing mark of laboratory studies. More often, and particularly in the older infancy work, the laboratory was a setting for carefully controlled and systematic observation rather than a place to carry out experiments of canonical design. For instance, the early German work represented so well in Canestrini's (1913) monograph was sensitive to consideration of the regularity of stimulus presentation and uniformity of response re-

cording, but by and large each baby seen was offered as many stimuli as age and state of wakefulness would permit, in no regular order or design. Canestini reports on 279 acoustical stimulations in which he used 13 different sound-producing sources ranging from 7 occasions of "a strange person's whisper" to 53 presentations of a ringing bell. The germinal work of Pratt, Nelson, and Sun (1930) represented a further refinement of procedures of careful observation of the infant in a controlled context. Procedures of observation in a laboratory setting have continued to be used effectively, particularly in attempts to establish norms for development (Gesell, 1934, Papoušek, 1967) and in observations of states of wakefulness and sleep (Dittichová, 1964, Prechtl, 1958, Wolff, 1966).

Systematic psychophysical studies in which several values of a stimulus dimension are presented in a controlled fashion are relatively rare in the infancy literature. Jensen's (1932) investigation of the infant's response to taste and temperature has long stood as a model. In his observations on response to salt, for example, Jensen used five levels of salinity and repeated his presentation to each infant a large number of times. The revival of interest in early visual functioning that has characterized the last decade has led psychologists of infancy to new attention to the use of the strict psychophysical procedures (Heishenson, Kessen, and Munsinger, 1967).

The great bulk of random-assignment experiments on infants, those in the manner so common to general psychology, have been studies of learning. A range of studies from Maquis' (1941) study of activity change under modification of feeding schedule to Siqueland and Lipsitt's (1966) study of conditioned head-turning represents the common characteristics of experiments with infants. The use of procedural paradigms tested with animals and adults, close attention to control of the stimulus conditions and the quantification of response, and generally a commitment to an associationistic view of the child are shared characteristics of experimental studies of the newborn, as they are of experimental studies of the older infant (Rheingold, 1956, Papoušek, 1967, Brackbill, Fitzgerald, and Lintz, 1967).

A powerful but rarely used application of experimental design is the co-twin study in

which one member of a twin pair is given training or exposure to stimulation which is not available to his sibling (Gesell and Thompson, 1929, Strayer, 1930).

The carefully controlled experiment, with suitable comparison groups, remains one of the most precise instruments available to students of infancy. However, its precision and ultimate utility are constrained by the relevance and generality of the questions posed to the procedure and it is difficult to resist the conclusion that many experimental studies of infant behavior are regularizations of common sense, or, worse, laboriously magnified observations that have the scope of a single developmental test item. It should also be noted that even the most carefully managed experimental studies confound treatment with the effects of age, a general characteristic of child study which is amplified by the rapid development of the infant in the first 18 months of life.

Other Systematic Procedures

Observation in Natural Settings The work of the European animal ethologists (Tinbergen, 1951, Lorenz, 1966) has led to the application of ethological attitudes and procedures to the study of infants. The work of Ambrose (1961) and of Spitz and Wolf (1946) on smiling, of Bowlby (1958), Robertson (1962), and Schaffer (Schaffer and Emerson, 1964) on early separation and the origins of anxiety, and the work of Ainsworth (1963) on mother-attachment define the evolving tradition. Clearly, studies of this order share many characteristics of procedures described earlier but the ethological dedication to the analysis of naturally occurring phenomena, resting as it does on a unique theory of the child, warrants separate mention.

Retrospective Studies Freud's epochal theory of the nature of early infancy is a monument to the use of retrospective studies to draw conclusions about the first months of life. His methods of inquiry and procedures for inference continue, *mutatis mutandis*, in the work of contemporary psychoanalysts (clinical studies in *Psychoanalytic Study of the Child*, *passim*). In addition to retrospective studies of infancy based on the recollections of patients in therapy, there is a substantial body of literature about infancy

drawn from the recollection of parents Sears, Maccoby, and Levin's *Patterns of Child Rearing* (1957) is a model for the strategy

Cross-Cultural Studies Anthropologists, particularly those influenced by psychoanalysis, have long been interested in variation among cultures in patterns of early development and of early mother-child interaction (Mead, 1954, Whiting, 1963, Whiting and Child, 1953) Interest in cross-cultural comparison continues to the present, with a particular interest on Africa (e.g., Ainsworth, 1963, Geber and Dean, 1959) and such study has been given important support by the establishment of cooperative groups such as the *Centre Internationale de l'Enfance* (Falkner, 1966)

SEVERAL VIEWS OF THE INFANT

The diversity of methods used to study infancy is well matched by the diversity of conclusions drawn by investigators about the nature of the young child Because of our limited access to the infant over so important a period of his development, because students of infancy come from several disciplinary homes and with widely varying theories, explicit and implicit, about the nature of man, and, centrally, because the human infant is so rapidly changing a phenomenon and so variable a source of data, a visitor from another planet who selected randomly from the enormous literature on infancy would be hard-pressed to recognize that a single species was under examination Such diversity is not regrettable Perhaps our best hope for understanding the infant depends on our approaching him from several sides and with several procedures In order to comprehend the pluralism of infancy studies, we have divided an overall guide to the bibliography into the following sections—the infant as an *assembly of reflexes*, the infant as *emerging behavior*, the infant as *sensory surface*, the infant as *learner*, the infant as *perceiver and thinker*, and the infant as *social partner* Necessarily somewhat arbitrary, and unhappily obscuring the overlap that exists among categories, the divisions can be defended, at least as a device for sorting studies and at best as collecting together closely related attitudes toward the nature of

the child and the proper procedures for understanding him

The Infant as an Assembly of Reflexes

The remarkable density of studies of reflex activity in the newborn and the young infant may plausibly be understood on several grounds First, scientific physiology in the nineteenth century—that is, the physiology of Helmholtz, Dubois-Reymond, and their students—depended heavily on the reflex as the fundamental unit in their conception of man (see Fearing, 1930) Many of the academic neurologists who played an important role in early studies of newborn behavior were clearly in the Helmholtzian mold Neurologists saw the reflex as the clearest window on the diagnosis of brain function Second, although Wundt and many of his American students did not consider reflexive behavior to be a proper part of psychology, the incorporation of Russian reflexology into American behaviorism made the study of reflexes an important part of developmental study Finally, and perhaps of greatest relevance, the clarity and regularity of reflex behavior stood out from the otherwise chaotic and confusing activities of the newborn infant in a way that made the reflex appear to be the obvious and systematic way to understand the young infant

Lists of Reflexes The taxonomic task—the description of infantile reflexes—sometimes takes on the character of *list-making* Cattaneo (1902) described six reflexes and their variation in a pathological sample over the first two years of life, Burr in 1921 and DeAngelis in 1923 listed “the” half-dozen reflexes of early infancy, among Blanton's (1917) several dozen responses of the first month were nearly a score that could be seen as reflexes, Dennis (1934), the chief bibliographer of infancy in the 1930s, brought together a list of almost 100 responses of the newborn infant, many of which were reflexes Descriptive aspects of the work of André-Thomas and Saint-Anne Dargassies (1960, 1962), the encyclopedia of Peiper (1963), and the standard texts of pediatric neurology (e.g., Dekaban, 1959) add richly to our collection of reflexes A few patterns appeared in almost everyone's list—patellar and abdominal and cremasteric reflexes, reflexes of the foot, reflexes of feeding (especially root-

ing, sucking, and swallowing) and crying and grasping, and reflexes of the whole body (startle and Moro). Yet, beyond these favorites, investigators have given concentrated attention to a staggering variety of reflexive patterns. To illustrate by sampling, Alexander (1911) described the nystagmic response to active and passive turning of the baby's head, Hollis (1913) described the facial grimace of the child about to cry, Thornval (1921) treated of the nystagmic response to water of varying temperatures placed in the child's ear, Bauer (1926) described the newborn's primitive crawling, Wagner (1938) noted the temporal characteristics of hiccups, Stirnimann and Stirnimann (1940) assessed the grasping reflex of the foot in 1000 infants, Lønnum (1956) compared the abdominal skin reflex in newborn infants with its appearance in brain-damaged adults, Mitchell (1962) presented early developmental data on the Landau reflex (a regular response of infants to ventral suspension), Parmelee (1963) described Babkin's hand-mouth reflex in prematures, Zapella (1963) studied the appearance of foot-placing in children under 2 months of age, Prechtl, Grant, Lenard, and Hrbek (1967) made a polygraphic study of the lip-tap reflex, and Schmidt, Leurs, and Weidtmann (1968) presented over 600 observations of children in the first 9 months of life on the reflexive response of the infant's head and back to the stimulus of being flicked on the nose.

Of course, almost all investigators of reflexive behavior in the young infant were sensitive to two limitations in the view of the child as an assembly of reflexes. First, not all behavior, even in the newborn baby, could be conceived as reflexive. The earlier discussion of general activity (see especially the work of Bryan, 1930, Gilmer, 1933, and Pratt, 1936) illustrates the troublesome problem of "spontaneous" activity. Moreover, a number of attempts to contrast *reflex* and *instinct* that appear in the literature from before Stern (1914) to after Bowlby (1958) illustrate the problem of mixed categories. Second, sensitive observers of behavior that can usefully be called reflexive recognized that wide variability exists, from occasion to occasion and from baby to baby, in the stability and reliability of the relation between stimulus and response. For example, observa-

tions made in several laboratories on movements of the head when the baby lies on his stomach indicate both the complexity of the response and the variety of variables that influence it (Prechtl, 1958, Turkewitz, Gordon, and Birch, 1965a, 1965b). To be sure, the alert infant stimulated on and near the mouth will move his head from side to side and will often open his mouth and grasp the stimulating object with his lips. However, it has been observed that the response not only changes with age (e.g., in the definition of the area near the mouth that will evoke the reflex) but also that the response varies widely during a single observation in amplitude and frequency, that the likelihood of eliciting the response depends on the sleep state of the baby and on time since last feeding, and that there is evidence for adaptation of the reflex under repeated stimulation. Prechtl (1958) has attempted to encompass part of the variability in head-turning by distinguishing a fixed-form response—side-to-side movement—from a variable form response—directed head-turning. It is a uniform finding in the literature that comparable complexity is found in other reflexive behavior when a close examination is made of response topography and conditions of elicitation.

Several groups of reflexes, at one time or another over the past 30 years, have received close attention from pediatricians, neurologists, and psychologists. The reflexes of feeding hold first place among these (see, in particular, Peiper's (1963) remarkable treatment of the relation among sucking, swallowing, and breathing) and a later section of the present chapter will treat sucking in detail.

The Babinski Reflex. As noted earlier, the reflexive movements of the foot—*plantar* and *Babinski*—have been favored objects of study. The Babinski remains an important index of abnormality in the functioning of the adult central nervous system (Nathan and Smith, 1955) but attempts to find clear-cut developmental patterns have been generally unsuccessful. Bendix (1931) had remarked on the relative variety of the Babinski in newborn infants and the work of Pratt (1934a, 1934b, 1934c) demonstrated in thousands of observations the variability of the response of newborn infants to plantar stimulation. Observing eight anatomical segments of leg and

foot, Pratt found it necessary to list eight different patterns of response in order to account for just half of the obtained reactions. Pratt also demonstrated a variability in the response dependent on variation in stimulus and variation in state and his conclusions were generally confirmed in an exhaustive analysis of the literature made by Richards and Irwin (1934).

The Moro Reflex as Representative Example Close to the Babinski in level of interest aroused among students of the infant is the embracing reflex (*Umklammerungsreflex*) described in 1918 by Moro. Consideration of the Moro reflex will lend support to the conclusion that striking changes have been made over the intervening 50 years in technical procedures for studying infants. Moro described the response as comprising a symmetrical moving of the arms away from the body followed by a return of both arms to midline; he reported that the reflex was elicited by sharply hitting the surface on which the child lay and he speculated that the response represented a primitive tendency of the infant to clasp and cling to the mother. In support of his more general proposition that the first three months of life represented a time of utter helplessness and dependence, Moro noted the disappearance of the *Umklammerungsreflex* in the second quarter of the first year. Every aspect of Moro's somewhat offhand description of the response has been studied in substantial detail. Confusion of the Moro response with startle patterns similar to the startle response of adults continued in the literature (e.g., Irwin, 1932; Wagner, 1938) until the careful photographic work of Hunt and his colleagues demonstrated that the Moro and the startle pattern were distinguishable characteristics of infant behavior (Hunt, Clarke, and Hunt, 1936; Clarke, Hunt, and Hunt, 1937). As Moro had suggested, the response he described is common in the newborn period and shortly thereafter but becomes less easily observable in the third month and, except in premature and damaged infants, has generally disappeared by the fifth month of life. The startle pattern, on the other hand, is rare during the first weeks of life (although it can occasionally occur as if superimposed on the Moro), increases in frequency and stability during the first years of life and becomes generally in-

distinguishable from the adult startle pattern. McGraw (1937) treated the disappearance of the Moro and the appearance of the startle as the development of a single process, but her findings are compatible with the interpretation made by Hunt.

Argument has persisted too on the adequate stimulus for eliciting the Moro response. Besides the original disturbance to equilibrium, it has been observed that loud sounds, changes of position, and changes of temperature will also provoke the reaction (see Mitchell, 1960, for a summary statement). Peiper has maintained that the vestibular apparatus was critical in stimulating the response while André-Thomas has supported the involvement of stretch receptors in the muscles of the neck. Apparently critical studies reported by Precht (1965) indicate that either stimulus will produce the Moro even in the absence of the other.

The functional significance of the Moro reflex remains in some doubt. Although some commentators have argued with Moro's interpretation of the response as related to primate clinging (Goldstein, Landis, Hunt, and Clarke, 1938), recent observations by Precht (1965) suggest that Moro was not far off the mark. Precht found that when head-drop stimulation is given an infant while his palmar grasp reflex is being stimulated, the "clinging" component of the response is strongly facilitated. Precht is of the opinion that the conditions under which the response is ordinarily elicited are not biologically adequate but that, were the baby clinging to a maternal surface, loss of support would properly elicit increased abduction and grasping. The 12-channel electromyographic record that Precht uses to support his conclusion is a long distance from Moro's brief verbal sketch and we surely know far more about the precise conditions of elicitation and the precise form of the response than was known 50 years ago. It is, however, not altogether obvious that our understanding of the Moro response in the context of the baby's other behavior has been significantly advanced.

The Grasp Reflex Study of the infantile grasp reflex shows, perhaps even more strikingly than the Moro, the process of *making precise* what was a relatively casual but accurate observation. An English medical officer named Robinson reported an "infantile

atism" in 1891. He reported that newborn infants could support their own weight when suspended and he published a photograph of a child clinging to a leafy tree branch in expression of Robinson's conviction that the response was related to our having a "quadrumanous ancestor." The grasp response was noted by many investigators and Richter (1934) systematically observed that the newborn human being could hang by two hands for a minute or so, although there was the usual great variability from subject to subject and from occasion to occasion. Myrtle McGraw (1940) observed nearly 100 children between the newborn period and 7 years of age to demonstrate the triphasic development of the reflex. She found for grasping, as she had found for the Moro-startle pattern, that the infant's ability to support his weight was relatively high during the first weeks of life, declined to a very low level after the first half year and then became steadily better in "voluntary or deliberate" suspension from age 1 to age 7. In her sample, children did not achieve again until age 5 the capacity to support themselves that was characteristic of a baby at age 40 days. The gains since Robinson's observations have been substantial and largely in refinement of early accounts.

Reflexes, the Brain, and Psychology Moro's emphasis on the importance of the first three months of life for nervous system development reflected the general opinion among neurologists, best expressed by Flechsig (1920), that the newborn was unfinished and that birth marked only a midway point in the myelination and functioning of cerebral pathways. The process that began in the fifth fetal month neared its completion only in the fourth postnatal month. Although a few radical behaviorists spoke of learning reflexes (Hollingsworth, 1928; Kuo, 1924), many observers of the young infant believed that the changes in behavior observed during the first months of life could be largely ascribable to anatomical changes in the central nervous system (see, for example, Catel, 1932, who referred to the newborn as "an incomplete and helpless creature"). Much of the interest in the infant as an assembly of reflexes has derived from the concern of neurologists to chart normal development and, even more critically, to detect pathological development.

The work of Peiper (1963), of André-

Thomas and Saint-Anne Dargassies (1960, 1962), and the continuing concern of neurologists in reflexive behavior (Dekaban, 1959; Fiorentino, 1963) are, in large measure, attempts to build a research basis for clinical neurology. The infant in the early weeks of life, in this view, has been seen as a structurally incomplete organism (Conel, *passim*) and the observation of reflexes has been in demonstration of cerebral insufficiency. Even André-Thomas, sensitive to the continual development that connects early infantile behavior with the complexity of the older child, wrote about the instability of the baby's "first impressions" (André-Thomas, 1954), and Peiper (1963) is unequivocal in his conclusion that the "mature newborn infant is a pallidum creature without functional cerebral hemispheres" although "the most important neurological differences between newborn infants and adults have already disappeared at the end of the first year of life."

What then is the place of the reflex in the psychology of early infancy? Is the enormous literature on reflexes to be seen as reflecting merely the life-keeping economy of the young child, a collection, in Prechl's keen phrase, of "phylogenetic relicts"? Titchener long ago posed the issue sharply.

The human infant, in particular as the incomplete form of a very highly developed organism, embodies two courses of development, a phylogenetic and an ontogenetic, in their most complex modes. The newborn child hangs to your finger, supporting its full weight upon its arms, the boy, a few years later, will hang in like manner from the horizontal bar. While both performances are conditioned on racial inheritance, the later is not the direct outgrowth of the earlier, and we should go widely astray if we argued from likeness of form to continuity in ontogenesis (1909).

At the very least, Titchener's implied request for an empirical demonstration of the connection between behavior in the first weeks of life and later characteristics of human beings has not been persuasively answered. Reflex behavior plays a role in the study of the child as emergent behavior, as a marker of sensory competence, as the first link in studies of learning, and as a theoretical idea

of some power in the work of Piaget. Yet, sucking aside, the literature of infancy is strangely quiet about demonstrating the continuity, for the *normal* child, between early reflexive behavior and significant social and cognitive behavior of later life.

The Infant as Emergent Behavior

Emergent behavior is proposed as a category to contain responses which develop in a regular age-related fashion through the first 18 months of life. The development of prone locomotion is the prototypical example, perhaps, of emergent behavior. Arnold Gesell was certainly the chief architect and polemicist of the view of the child as a system of naturally emerging behavior. Gesell's interest, like that of the neurologist of early reflexive behavior, was to chart the course of changes in behavior uniformly characteristic of the human species and tightly tied to age.

All things considered, the inevitableness and surety of maturation are the most impressive characteristic of early development. It is the hereditary ballast which conserves and stabilizes the growth of each individual infant. [Without it] the infant would be a victim of flaccid malleability (Gesell, 1928).

Certainly Gesell had reason to be enthusiastic about age-related behavior in infancy. Even a casual survey of the developmental tests mentioned earlier in this chapter provides a long list of responses that share two critical characteristics—very nearly universal appearance in human beings and a very sharp rise in probability of occurrence as a function of age. Among the countless possible examples, consider a typical observation by M. C. Jones (1926) (no radical maturationalist!) made on a group of several hundred American children. Of the babies studied, 25% blinked at the approach of an object by the end of the second month, 75% blinked at the end of the third month, the dates of the first and third quartiles in Jones' sample for sitting were 205 days and 250 days, and other examples can be supplied at length. Of course, the regularity of occurrence does not explain itself; students of infancy remain divided in the emphasis they give to autoch-

thonous physiological factors, on one hand, and to species-general uniformities in the environment of young children, on the other. Whatever the point of departure, however, the study of the infant as emerging behavior has been a major theme of psychology through the twentieth century. In addition to the normative studies described earlier—those largely aimed at the construction of test items—there are a large number of more highly focussed and detailed studies of emergent behavior in the literature. The following sketch of several areas of investigation will serve to illustrate the range of method and findings.

Prone Progression. Tietjen (1900) analyzed about 200 responses to a syllabus (questionnaire) of G. Stanley Hall's on creeping and walking. Although his conclusions may seem somewhat overdrawn today—for example, he maintained that, in assuming the upright position, man expresses "the limit of organic evolution"—his observations on the sequence, timing, and variety of locomotor responses conform to later reports. Careful tracings of motion photography permitted Buinside (1927) to describe the topography of early locomotion in fine detail. The two classic studies of locomotion appeared in 1940. Gesell and Ames (1940) used motion photography to distinguish 23 stages of prone behavior organized into 4 cycles during the first 60 weeks of life. The first cycle ended with pivoting on the stomach at about 30 weeks, the second with creeping at 45 weeks, the third with "plantigrade progression" at 50 weeks, and the fourth with walking at 60 weeks. Gesell and Ames also attempted to give some interpretation to their observations by the use of the spiraling notion of *reciprocal interweaving*. McGraw (1940) organized her 3000 observations of 82 infants in the first 5 years of life to demonstrate 7 "distinct phases" in the development of locomotion from reflex stepping in the newborn to the mature walking characteristic of children at the beginning of the third year. Like Gesell and Ames, she put the peak time of "deliberate stepping" at about 60 weeks of life. McGraw's study at once illustrates the regularity of behavioral sequences in young infants and the economy of description possible when scoring categories are carefully selected. The explanatory scheme imposed on her data by McGraw involved quasi-neurological con-

siderations of cortical inhibition and integration. Studies of motor development that concentrate on the first months of life (e.g., Bergeron, 1938, 1948) have emphasized the stabilization of behavior at about three months that has been so commonly observed in reflexive behavior.

Although, as noted earlier, racial or cultural differences have been found in earlier motor behavior, sketchy available evidence suggests that age of walking is a remarkably stable *human* characteristic (Smith, Leckel, Dunlap, and Cureton, 1930) except under conditions of great deficit of environmental support (Dennis and Najarian, 1957).

Prehensile Skill The work of Halverson (1931-1937) on grasping patterns in the first year of life is perhaps the most carefully documented account of emergent infantile behavior. Based largely on the analysis of photographic records using both longitudinal and cross-sectional procedures and presenting the child with varying stimulus materials, Halverson has presented verbally and pictorially a very nearly full description of early prehension. Other investigators have gone beyond Halverson's taxonomic account of sequence and topography. Stummann (1941), noting the differences between the newborn's grasp of a human finger and his grasp of similar artificial stimuli, concluded that early grasping must be understood as the first expression of a social drive. In a preliminary report of research, Bruner (1968) again has emphasized the important role that the interaction of grasping, vision, and sucking play in early development of mind (see also Piaget, 1936, 1937). Studies of bilaterality and early hand-preference have shown that early bilaterality observed in the tonic-neck reflex (Ames, 1949) is succeeded by a period of mixed preference with clear tendencies for a single hand to be more active emerging only after 6 months of age (Lippman, 1927, Ames, 1949, Flament, 1963, Haith, Kessen, and Collins, 1969). Some evidence suggests that handedness is related both to genetic and to intrauterine factors (Churchill, Igna, and Senf, 1962).

Crying and the Development of Affect The study of early emotional development shows none of the clarity and stability that characterizes studies of locomotion and prehension. Newborn crying has been described

in some detail (Aldridge, Sung, and Knop, 1945a, 1945b, 1945c, Aldridge, Norval, Knop, and Venegas, 1946) with the data indicating the relevance of feeding cycle (babies cry most just before feeding), the sensitivity of crying to care-taking routines (crying can be halved by moderate increases in amount of nursing care), and the absence of contagion from the crying of one infant to that of others. Crying has been shown to be inhibited both by feeding (Marquis, 1943) and by nonnutritive sucking (Cohen, 1967). There is formal evidence in support of the common observation that crying can be reduced by holding the baby (Peiper, 1963) and by continuous auditory stimulation (Salk, 1961, Brackbill, Adams, Crowell, and Gray, 1966). Attempts to find evidence linking amount of crying to characteristics of delivery have been generally unsuccessful (Ruja, 1948).

The development of technically advanced devices for recording the sounds of crying (Fischelli, Karelitz, Eichbauer, and Rosenfeld, 1961) promises more differentiating observations on early crying. The relation of crying and other early vocalizations to infant speech has been examined by Lewis (1951), Murai (1960), and Bullock, Jones, and Bever (1964), among others.

The peculiar asynchrony between the infant's reflexive response to a painful stimulus and his later crying has been noted (Taylor-Jones, 1927, Peiper, 1963) and the proposal has been made that motor and autonomic components of the infant's response to pain may be initially somewhat independent (Levy, 1960, Kessen and Mandler, 1961). The most systematic treatment of the development of affect in the first months particularly in relation to pain has been given by André-Thomas (1954, André-Thomas and Autgaerden, 1959). He describes the change from early polar extremes of *affect* (simple approach and withdrawal) to later subtle and socialized *affectivity* (affection and sympathy on one side, defense and counterattack on the other). Other attempts to make some sense of early affective development have been made by Schmale (1964) and by Spitz (1965). Schmale (1964) emphasizes the primacy of anxiety as affect and charts a possible course for the development of the infant's sense of helplessness. Spitz proposes that three "organizers," comparable to the physiological or-

ganizers of embryological development, mark emotional change in the first year of life. The baby's first social smile, his anxiety at 8 months, and his head-shaking sign of negation are, in Spitz's view, benchmarks for early emotional differentiation.

With the exception of smiling and other signs of attachment, the empirical base for the early differentiation of emotional expression is shaky. Most secondary sources depend on the work of Bridges (1931-1937), who described a differentiating branching of emotional expression from initial excitement to later excitement and distress to still later excitement, distress, and delight, and finally to a wide range of emotional expression at 2 years of age (Bridges, 1932). She proposed an analogous ontogenesis in primary drives (Bridges, 1936). Acceptance of Bridges' simple scheme must be guarded by consideration that her samples were small, that the children observed were institutionalized foundlings, and that criteria for assignment to categories were ill-defined. Darwin's (1877) and Miss Hall's (1896, 1897) biographical accounts of emotional development are more persuasive than Bridges' apparently systematic assessment, a contrast which dramatizes the need for an adequate descriptive account of emotional development in infancy.

Sleep With the care for detail characteristic of her time, Wagner (1937, 1938, 1939) studied newborn sleep. She used records of gross movement, eye movement, and mouth movement to establish seven levels of the sleep-waking dimension and she assessed the infant's responsiveness under each level of stage to stimuli in several sensory modalities. In spite of wide variability within and between subjects, she found that deep sleep (the condition of infants about 13% of the time) was relatively easy to judge, that "body jerks" were most frequent in light sleep, and that the baby was uniformly more responsive as motility increased. Reynard and Dockeray (1939), on evidence from stabilimetric records, concluded that "complete waking" and deep sleep were easily recognized and tended to persist over time but that no clear transition patterns could be established for their five intermediate stages. More recently, Brown (1964) and Wolff (1966) have proposed quite similar categorizations of sleep-waking with emphasis on patterns of respiration and

motility. Wolff's observations led him to conclude that the infant is likely to be responsive to external stimuli more during intermediate states than while deeply asleep or very active and that spontaneous motor patterns such as startles, mouthing, sobbing respirations, and erections occur rhythmically and most often under conditions of minimal external and visceral stimulation. Electroencephalographic markers of the development of sleep over the first 18 months of life have also been reported (Muzoyants, 1961).

Studies of the development of sleep patterns in the first year of life reveal some congruent findings. Children in the first weeks of life sleep between 14 and 15 hours each day (Irwin, 1934; Kleitman and Englemann, 1953; Parmelee, Schulz, and Disbrow, 1961), within the major diurnal rhythm there appear a number of minor rhythms. Night sleep goes from about 60% of the total in the first weeks to about 80% or even higher at 18 months (Irwin, 1934; Kleitman and Englemann, 1953). The duration of the longest single period of sleep (on a criterion that included light and deep sleep) increases from about 4½ hours in the first days of life (Parmelee et al, 1961) to over 10 hours by the twenty-fifth week (Parmelee, 1961). Regular cycles of shorter duration also appear. Tchong and Laroche (1965) found, in children up to 2 months of age, cycles of activity that lasted about 70 minutes. Periods of deep sleep approximately 21 minutes long were bounded on either side by periods of "half-sleep" of approximately equal duration. Their findings are congruent with those Asemsky and Kleitman (1955) who, on criteria of gross motility and eye movements, described deep-sleep periods of about 24 minutes within a more variable motility cycle of about 1 hour, and with those of Weitzman, Fishbein, and Graziani (1965). Dittichová (1964) observed 12 infants over the first 24 weeks of their lives. She reported dramatic and abrupt changes in the third month of life when babies begin to manipulate toys, begin to vocalize comfort sounds, and decrease their crying markedly. Hellbrugge, Lange, Ehrengut, Rutenfranz, and Stehr (1964) have drawn together available evidence on sleep and other circadian rhythms and have concluded that, although the sleep-wake cycle begins to stabilize in the third week of life,

the natural periodicity of the newborn infant (approximately 24.4 hours in duration) does not become adapted to a 24-hour cycle until well into the sixth month of life. Roffwarg, Muzio, and Dement (1966) have presented evidence that rapid-eye-movement (REM) sleep (so-called "dreaming" sleep) occupies almost half the sleep time of newborn infants and decreases rapidly to about one-quarter of the sleep time of children of 2 years. They propose, in explanation of so puzzling a finding, that endogenous neural activity underlying REM sleep prepares the higher centers of the late fetus and newborn "to handle the enormous rush of stimulations" encountered after birth.

Besides the empirically demonstrated patterns of emerging behavior in infants, only a small fraction of which are represented in the foregoing account, there are implicit or asserted propositions about age-related change (*maturation*) in all theories of psychological development. In the psychoanalytic theory of psychosexual development (Freud, 1905, Erikson, 1955), in Piaget's account of cognitive development (Piaget, 1936), and among the psychologists primarily interested in learning (e.g., Spiker, 1966) recognition has been shown, with greater or less precision, of the importance of species-general and age-related changes in early behavior that cannot be positively accounted for with available models for environmental impact. In the specialized studies of particular emerging behavioral patterns and in the more general catalogue of the developmental test, a detailed profile of early human development can be seen.

The Infant as Sensory Surface

Beyond the clinical concern with adequate functioning of sensory systems in the infant, there are two related intellectual sources of psychology's concern with the infant as a sensory surface. The antecedents of academic psychology in the sensory physiology of the nineteenth century joined well with the systematic associationism of American psychology that looked for all important behavioral control in the history of environmental impact. From Preyer's (1880) careful treatment of sensation to the present, there has been a connected tradition of research on the infant's sensory capacities.

The earlier discussions of reflexive and

emergent behavior necessarily involved a recognition of sensory process. The vestibular change that elicits the Moro response, the bright light that causes pupillary contraction, the dangling ring or the pile of cubes that are presented in a developmental test, and the parental command all measure to some degree the infant's ability to detect and process sensory information. Early reflexive behavior, in particular, involves the infant's ability to respond to labyrinthine, deep-touch, and kinesthetic stimulation. A survey of the classical literature on the reflexes and on emergent behavior might, taken altogether, provide an index to the infant's receptive capacities. However, so attractive a solution is not feasible for at least three reasons. The literature represented in the preceding two sections does not commonly use standard stimuli, it only rarely involves comparable response measures, and it is generally insensitive to variations in the state of the infant and the context of stimulation. These limitations are shared with many investigations aimed directly at the study of sensory function. Moreover, as will be seen, many studies of infantile sensation give insufficient room to epistemological issues and to parametric variation. The first of these problems was alluded to earlier in a discussion of the contrasts among stimulation, world, and reality. Psychologists of infancy will probably miss some of the most fascinating problems of early development and, more, they may be led into error if they assume that the surround of the infant can be most economically organized in terms of physicalistic description of stimuli or in terms of common objects.

Although the epistemological difficulties seem esoteric and dispensable to empiricist psychologists, the variety of parametric study of stimulus dimensions cannot be lightly ignored. After a century of research, it is no longer profound to assert that the young infant responds (or does not respond) to a particular configuration of the environment. A full account of infancy requires, rather, systematic variation of environmental variables, in the blessed case, the dimensions of variation are drawn from a conceptual analysis of the baby's nature.

Excellent summaries of the literature on sensory functioning in the newborn and young infant are available and no attempt will be

made to duplicate them here Preyer (1880) presents a good summary of nineteenth-century and earlier studies, Peiper (1963) brings together European studies up to 1950, and Pratt's (1954) chapter on the newborn in the second edition of *Carmichael's Manual* concentrated heavily on the sensory capabilities of the infant. Work since the mid-1950s has not been uniformly distributed across age or modality. The characteristic primacy of newborn studies continues and, even more strikingly, *vision* has received more attention than all other sensory channels. Because early visual development has been at a focus of recent research and because a detailed treatment of vision illustrates more general problems of method and inference, a later section of the present chapter will be given over to a consideration of research on early visual development. Here, audition and the other senses will be treated briefly.

Audition. From Preyer's (1880) first doubts about the newborn infant's ability to hear at all, there has been a connected series of studies by physicians and psychologists on auditory functioning in the infant. As usual, the range of interest is from clinical procedures for detecting deafness to issues of epistemological implications about the infant's first conceptions of space.

Clinical Tests of Hearing. All techniques used to study audition in the infant are, in a sense, available for clinical application, but some investigators have focused sharply on the problem of devising ways of diagnosing hearing loss early in infancy. Demetriades (1923) reviewed the available work on hearing and added his own observations that most children would blink to the sound of a tuning fork within the first 24 hours of life. Conditioning of foot-withdrawal was used by Aldrich (1928) to show auditory sensitivity in a 3-month-old child. Typical of screening procedures used are those described by Fioeschels and Beebe (1946), who found a positive response of almost all then observed newborns to complex whistles, and by Hardy, Dougherty, and Hardy (1959), who studied the capacity of a large number of complex sound makers to distract children in the first weeks of life. Recently, Goodman, Appelby, Scott, and Ireland (1964) and Weitzman, et al (1965) have used computer-analyzed EEG responses to repeated sounds as an index

of auditory sensitivity. In both studies, all newborn infants observed showed a recognizable evoked response. Richmond, Grossman, and Lustman (1953) returned to blinking as a response to intense (113 db) sounds as evidence for infantile hearing.

Dimensions of the Stimulus. To what aspects of the auditory stimulus is the infant sensitive? A clear answer to so reasonable a question is difficult for several reasons. Often researchers have used complex natural sounds that do not submit readily to dimensional analysis—the squeak of a rubber rat (Miller, Schweinitz, and Goetzinger, 1963), the cinkling of paper (Eisenberg, Griffin, Coursin, and Hunter, 1964), and miscellaneous “sound-makers” (Ewing, 1947). Even when some care is taken to specify the stimulus, however, variation in the conditions of observation make impossible the statement of parametric values (see Eisenberg, 1965, for a discussion of problems in controlling auditory signals). Consider the baby's response to variations in *frequency*. Marginal differential responses to frequency variation or none at all have been reported by Stubbs (1934), who observed breathing and activity changes, by Keen (1965), who observed sucking, by Goodman et al (1964), who observed evoked cortical potentials, and by Leventhal and Lipsitt (1964), who observed changes in movement and breathing. On the other hand, Haller (1932) reported that infants were disturbed by high pitch, Bronshtein, Antonova, Kamenetskaya, Luppova, and Sytova (1958) reported rather fine tuning of sucking-inhibition to variations in frequency, Eisenberg et al (1964) reported that high-frequency sounds provoked unique behavior, Eisenberg (1965) suggested that the infant is differentially tuned to frequencies in the range of human speech (500–900 cycles per second), and Birns, Blank, Bridger, and Escalona (1965) reported that a low-frequency tone (perhaps 150 cycles per second) more effectively inhibited behavior than did a high-frequency tone (500 cycles per second) in infants under high arousal. Kasatkin and Levikova (1935) used conditioning procedures in showing that 3-month-old infants could differentiate pure tones about an octave apart. The studies cannot be systematically compared with one another and no study—with the possible exception of Bronshtein et al (1958)—is of

sufficient scope to justify a summary statement about the infant's sensitivity to frequency

Somewhat less ambiguous statements can be made about the infant's response to *intensity* of sound although here, too, interpretation is made difficult by the existence of unknown differences among laboratories, particularly in the level of ambient baseline noise. Early investigators (e.g., Froeschels and Beebe, 1946, Haller, 1932, Stubbs, 1934) agreed that a high-intensity tone was more likely to provoke a response by the baby than a low-intensity tone. More recent studies have moved toward the statement of more subtle functional relations. For example, several studies suggest that infants increase their likelihood of response quite sharply at about 60 decibels of intensity, again assuming a relatively low level of ambient noise (Bartoshuk, 1964, Eisenberg, 1965, Steinschneider, Lipton, and Richmond, 1966). The relation between intensity and response for sounds above threshold has also been studied. Steinschneider et al. (1966) found that general motor responsivity increased with increasing intensity between 55 and 100 decibels and that aspects of the cardiac response also showed systematic change. Respiratory behavior also changed systematically with intensity (Steinschneider, 1968). From his finding of a relation between heart rate and sound intensity between 48 and 78 decibels, Bartoshuk (1964) fitted a power function to his results. Barnett and Goodwin (1965) found no systematic relation between cardiac change and intensity but they reported that the amplitude of a component of the cortical-evoked response changed linearly with stimulus intensity. The emerging simplicities become tangled again by suggestions that the baby's left and right ears differ in sensitivity and that he may show orientation *toward* relatively low-intensity tones and orientation *away from* high-intensity tones (Turkewitz, Birch, Moreau, Levy, and Cornwell, 1966).

A number of attempts have been made to assess the role of other stimulus dimensions—in particular duration (Keen, 1965, Stubbs, 1934) and complexity (Eisenberg et al., 1964)—but agreed-on summary statements have not developed. The great interest shown over the last decade in the habituation of the

infant's response to repeated sounds is recounted later in this chapter.

Orientation toward Sound The ability of children to turn their head and eyes appropriately toward a sound presented at their left or at their right seems to be well established by about 6 months of age (Chun, Pawsat, and Forster, 1960). The question arises, for a response so important to the organization of space, at what age and under what circumstances infants first show sound localization. Almost casual references to the newborn infant's orientation of head and eyes toward the source of the sound appear in the literature (e.g., Froeschels and Beebe, 1946) and interest in the issue was renewed by Wertheimer's (1961) observation of appropriate lateral eye-movement in a 10-minute-old child. Leventhal and Lipsitt (1964), in a study of adaptation and recovery of movement, found evidence of differentiation of location of sound. Following Schneirla's (1959) proposals about the relation of approach and intensity of stimulation, Turkewitz et al. (1966) showed a systematic relation between eye movement and location of auditory stimulation but had to call on differential sensitivity of the two ears in order to comprehend their findings. Turkewitz, Moreau, and Birch (1966) have further suggested that differential lateral responsiveness may be accounted for not so much by an innate connection between visual and auditory systems but by the asymmetrical position of the head (and assumed differential adaptation to ambient sounds) immediately before testing. With both electromyographic and photographic procedures available for the precise study of eye movements, further studies of early localization and its control are called for.

State, Arousal, and Quieting Uniformly, investigators agree that the baby's state of arousal or wakefulness is important in determining his response to sound stimulation. Pratt (1934), for example, found that whether the baby was wet or dry, awake or asleep, was far more influential than variation in stimulus characteristics. The difficulty of interpreting an increase in activity for a quiet baby and a decrease in activity for an active baby (whether as regression toward the mean or as representing the "law of initial value") appeared in Haller's (1932) observation that

her sounds caused more "comfort" responses in crying babies and more "discomfort" responses in sleeping babies and babies quietly awake. Stubbs (1934) found the greatest change in activity when the babies were awake and silent, less response when they were asleep or crying. With a very intense stimulus, Richmond, et al (1953) found blinking almost invariably in light sleep, less often in deep sleep, and least of all when the baby was actively nursing. Barnett and Goodwin (1965) found larger evoked EEG responses during deep sleep than during light sleep. Burns et al (1965) made their observations of auditory sensitivity only under conditions of high arousal. The complexities and confusions of the literature connecting auditory responsiveness to variations in state cannot be systematically clarified without further regularization of the indicators of variation in state.

The common observation that babies quiet to rhythmic stimulation has been subjected to more careful analysis in response to Salk's (1962) assertion that the infant was imprinted on the mother's heart beat. Salk observed that the presence of recorded heart beats during the first days of life resulted in increased weight gain and less crying. A failure to replicate Salk's findings by Tulloch, Brown, Jacobs, Prugh, and Greene (1964) used stimuli of such different intensity from his that a firm conclusion cannot be drawn. However, Blackbill et al (1966) have made careful controlled observations of the effects of rhythmic sound and have concluded that, although sounds demonstrably reduce crying and heart rate, no special virtue attaches to heart beat over other rhythmic sounds.

Changes with Age The response of fetuses to sound has been reported by Forbes and Forbes (1927) and by Sontag and Wallace (1935). Chun et al (1960) reported the increasing ability of infants in the first year of life to localize sounds and they concluded, as noted earlier, that the ability was clearly demonstrable at 26 weeks of age. Children of 3, 4, and 5 months of age were studied by Miller et al (1963) under stimulation with complex sounds. The procedure was held to be ineffective diagnostically for younger children but sensitive to developmental change in the period studied.

Individual Differences Stable individual

variation in the responsiveness of young infants to sounds have been reported by, among others, Burns (1965), Bridger (1961), and Steinschneider et al (1966).

Other Senses The volume of research on vision and hearing in young infants may not properly represent their importance in the economy of the child. Stone and Bakwin (1948) emphasized the role of experience in the development of vision and audition and asserted that "the other senses require no experience and appear to be highly meaningful to the young baby." The centrality of vision and hearing has also been denied by Baldenweck and Guy-Armand (1940), who made the even stronger assertion that "only the vestibular apparatus seems to be as adapted to its function at birth as it will ever be." Nonetheless, it is a fact of the literature that, although tactile sensitivity and kinaesthetic sensitivity are implicitly under study in a large number of investigations, systematic assessment of the senses other than vision and hearing have been rare.

In studies of *olfaction*, Engen, Lipsitt, and Kaye (1963) and Lipsitt, Engen, and Kaye (1963) reported changes in threshold to asafetida over the first days of life and differentiating response to acetic acid, anise, asafetida, and phenylethyl alcohol. Studies of olfaction, in infants as in adults, suffer from the difficulties of matching intensities of different chemical substances and from the unusually fast adaptation time of the receptor. Jensen's (1932) defining study of *taste* has already been described. Other studies of sensitivity to *temperature* change range from the effects of clothing on activity by Irwin and Weiss (1934) to Usoltsev and Terekhova's (1958) use of thermal conditioned stimuli. The Russian investigators found that both warm and cold stimuli showed broad generalization gradients and babies even up to 6 months of age had difficulty in differentiating among thermal stimuli. Crudden (1937) and Sturimann (1939) demonstrated that newborn infants respond to both warm and cold stimulation. Sturimann's conclusion that babies approach warm stimuli and withdraw from cold has not been replicated. Babies have also been shown to adjust the total number of calories taken in food with changes in ambient temperature (Cooke, 1952).

Tactile sensitivity is, of course, assessed

with every stimulation of the rooting reflex or the head-turning reflex and with stimulation to produce many other localized responses of the baby Lustman (1956) and Bridger and Reiser (1959) have used all-stream stimulation to assess body-part and individual variation in tactile sensitivity. Several investigators have examined the baby's response to electro-tactile stimulation. Lipsitt and Levy (1959) reported that electro-tactile threshold decreases over the first days of life and a study of Kave and Lipsitt (1964) showed that the early change in threshold could not be accounted for by changes in basal skin conductance. Evidence for habituation to electro-tactile stimulation (i.e., increase in threshold with repeated stimulation over the first days of life) has been presented by Gulickson and Crowell (1964). The possibility of a negative relation between muscle strength and tactile sensitivity, particularly as it may underlie sex differences, has been debated by Rosenblith and DeLucia (1963) and Bell and Darling (1965). The expectable influence of state on the baby's response to tactile stimulation has been found by Lewis, Bartels, and Goldberg (1967).

The assortment of studies reported in the treatment of infant as sensory surface is at once exciting and distressing. It has been clearly and repeatedly established that the normal newborn infant responds to stimulation in all sensory modalities, he is, in every sense, competent. Yet, demonstrations that the baby responds cannot substitute for careful studies of *how* response changes with variations in the dimensions of stimuli employed. Such study will require more attention to standardization of the stimulus and comparability of response and procedure than has been typical in the past. It is a measure of the need for research that we do not have valid curves of spectral sensitivity or audiograms or tactile threshold for infants. Nor is it a novelty to report that there are few studies of changes in sensitivity between the first few days of life and the time of rich and demanding differentiation made by the child near the end of the first year of life.

The Infant as Learner

Many strands come together in the study of the baby as someone who learns. The progressive and ameliorative attitude of the gen-

eral culture, the finely worked procedures of learning studies in animals, and the claims of philosophic empiricism in both its English and its Russian forms come together in a view of the child as defined by his encounters with the teaching environment. In addition to Stevenson's chapter in this book, several summary statements of the literature on early learning have appeared in the 1960s. Blackbill (1962) and Kasatkin (1968) have written reviews of Russian studies on infant learning, continuing the earlier summary by Razran (1933). Work by American scholars of early learning has been ably summarized by Lipsitt (1963, 1966, 1967) and by Horowitz (1968).

There can be no doubt that the behavior of the child changes with his experience during the first months of life, in this broad sense, he learns. In addition to the common observations of parents and the evidence of normative studies, the work of many investigators on early adaptation to feeding patterns can be cited (Call, 1964, Davis, Sears, Miller, and Brodbeck, 1948, Gunther, 1961, Piaget, 1936). Most laboratory studies of early learning, however, have more narrowly focused on demonstrations of the traditional paradigms of learning. The impact of early experience on children has, essentially, been pressed into three paradigmatic molds—classical conditioning, operant or instrumental learning, and habituation. Such a limitation of scope has the advantage of permitting a focused consideration of a group of theoretical and empirical issues and of supporting the comparison of studies from different laboratories. Clearly, however, the general utility of a learning analysis of infancy depends not only on the precision and comparability of the observations made but also on the degree to which the formal paradigms properly reflect the nature of the child. As will be seen, there has been an uneven evolution from excessive enthusiasm for the relevance of simple conditioning models for understanding development (e.g., Watson, 1925) to a recognition that early learning, in the narrowly paradigmatic sense, can be comprehended only in the context of the child's developing conceptual and cognitive abilities (e.g., Papoušek, 1968, Sameroff, 1969). Nonetheless, the traditional organization of the research on early learning will be maintained in this dis-

cussion Studies of classical conditioning and of operant learning will be treated here, a more detailed discussion of the phenomena of habituation will be presented later in this chapter

Classical Conditioning The study of classical conditioning in young children falls naturally into three periods of time Krasnagorsky's (1909) opening observations in 1907 on a single 14-month-old child were followed over the next 25 years by a number of studies both in the Soviet Union and in the United States His own work and observations of others led Krasnagorsky to the conclusion that only simple conditioned responses can be formed in the first half-year of life and that differentiated responses began to appear early in the second half-year Somewhat more extensive observations by Denisova and Figurin (1926) indicated that simple conditioned responses (depending on the context of observation and the stimuli used) could be observed as early as the beginning of the second month of life and they, too, observed differentiated responses in the sixth month These early Russian studies, among others, have been summarized by Razian (1933), invariably only a small number of children was involved in the studies and observations on required control groups were not reported In the United States, Macei (1918), studying conditioned mouthing in children between 1 and 7 years of age, found rapid acquisition and extinction of the response on the average, and a substantial correlation ($r \sim .60$) between age and rate of conditioning Watson's enthusiasms for a psychology based on reflex activity and especially his commitment to the conditioning of emotion (Watson, 1926) led to several observations on the relation of emotional development and conditioning procedures Among these were Watson and Watson's (1921) fabled and incomplete observations on a child named Albert, Jones' (1926) toleration extinction of fear in a 3-year-old named Peter, Jones' (1930) observation on 3 infants between 3 and 9 months of age that conditioned galvanic skin responses can be formed by shocking the babies, and Bigman's (1934) failure to establish conditioned emotions with a milder unconditioned stimulus It was also during this period of initial enthusiasms that Aldrich (1928) used conditioning procedures to diag-

nose hearing loss and that the radical behaviorists (e.g., Kuo, 1924, and Hollingworth, 1928) maintained that even the reflexes were learned

A second period in the study of early conditioning opened with Marquis' (1931) question, "Can conditioned responses be established in the newborn infant?" The application of a learning interpretation to early behavioral change demanded the demonstration that even the youngest child could be conditioned Marquis paired buzzer and feeding of eight infants during feeding periods over several days and found evidence of an increase in sucking and mouthing on presentation of buzzer alone Wenger (1936) attempted to show conditioning in young infants but used too few subjects to obtain stable results Wickens and Wickens (1940) observed responses to buzzer alone after paired buzzer and shock but found that a control group given shock alone showed the same pattern of response to buzzer that was shown by their "conditioned" group Marquis (1941) presented evidence for temporal conditioning in the changed activity of babies when they were shifted from a three-hour feeding schedule to a four-hour schedule During the 1930s, claims were also made for fetal conditioning in human beings by Ray (1932) and by Spelt (1938) The provocative observations made by students of perinatal conditioning were enough subject to alternative interpretation and to criticism on procedural grounds that Marquis' initial question could not be answered in the mid-1940s (Dennis, 1943) During this time, somewhat firmer evidence for conditioning was found for mouthing movements (Kantrow, 1937) and for defensive eye-blink (Morgan and Morgan, 1944) for children in the middle of the second month and older

The third, most vigorous period of interest in early conditioning has been over the last 15 years Researchers in the paradigm of classical conditioning have ranged widely and, among their studies of the newborn period alone, have touched on the change in leucocyte production with change in the temporal characteristics of feeding (Krachkovskaya, 1959), conditioned autonomic changes and facial expression to an unpleasant odor (Polikanina, 1961) sucking to the conditioned stimulus of a pure tone (Lipsitt and Kaye,

1964), and conditioning of the Babkin reflex to passive movement (Kaye, 1965). Conditioning in older infants has been reported for the orienting reflex (Kasatkin, Mizoyants, and Khokhitva, 1953), for eye-blink to a visual stimulus (Rendle-Short, 1961), for eye-blink differentiated to tone (Janoš, 1965), for pupillary dilation and contraction to a temporal interval (Brackbill et al., 1967), for the eye-blink to sound (Linz, Fitzgerald, and Brackbill, 1967), and for changes in visual preference (Lu, 1967). A study by Dashkovskaya (1953) can be taken as representative of the Soviet work during the period. A group of 10 infants in the first 10 days of life was given paired trials of a muffled electric bell and sugar solution, 10 infants had a red light paired with sugar solution, and 5 had bell paired with air-puff to eyes. For most children "distinct" but "unstable" conditioned responses appeared near the end of the period of observation after approximately 50 pairings of conditioned and unconditioned stimuli. Dashkovskaya pointed out individual variation among the infants, she noted the striking difference between normal infants and those with birth injuries, and she recounted the pattern of development of conditioned reflexes that Kasatkin (1968) has summarized in four stages. According to the Russian investigators, the course of early conditioning is seen in the change from (1) initial nonspecific responses to (2) a period of inhibition and orienting responses to (3) unstable conditioned responses and finally to (4) stable conditioned responses. Kasatkin summarizes a wide range of research (Brackbill, 1962) by asserting that "with a few exceptions, conditioned reflexes are weak and unstable up to the fourth to fifth weeks of life. A firm and well-expressed conditioned reflex is sometimes formed in the fourth week and almost always in the second month." Part of the variation is assigned to the conditioned stimulus used, both simple conditioned responses and differentiated responses occurring earlier for vestibular and auditory stimuli than for taste and visual ones. In a review of the literature on early conditioning, Lipsitt (1963) concurs with the conclusion that it is difficult to demonstrate aversive or defensive conditioning in the first weeks but that a far better case can be made for the early conditioning of appetitional responses, especially sucking. An at-

tempt to resolve the divergencies of the literature, recently made by Sameoff (1969), will be discussed later.

In any case, there is widespread agreement that conditioning becomes markedly easier as the child grows older. Kasatkin (1968) asserts that, whether pairing of auditory conditioned stimuli and either defensive or appetitional unconditioned stimuli is begun at age 10 days or age 30 days, stable conditioned responses will occur at the same time—at about 32 days of age. In a careful comparison of premature infants with full-term babies, Janoš (1958) found that stable conditioning occurred at the same *gestational age* in both groups with no advantage to the premature infants for their longer time in extrauterine life.

Operant Learning. The role of response-contingent reinforcement in early behavioral change lies implicit in early work (Myers, 1922, 1924, Watson, 1926), but systematic study of infants in the instrumental paradigm started late and American studies of operant learning in newborn infants are a genuine novelty.

The possibility of controlling amount of smiling in 4-month-old infants was demonstrated by Brackbill (1958) and the influence of adult smiling and touching on vocalization of infants in the same age range has been shown by Rheingold, Gewirtz, and Ross (1959) and by Weisbert (1963). Smith and Smith (1962) showed that children of about 1 year of age would work to change the orientation of their playpen in order to bring visual displays into view. The ability of year-old infants to respond differentially to lights of different colors when reinforced for hand-tapping by the appearance of chimes was assessed by Simmons (1964). Sigel and Sigel (1964) has shown that head rotation to left or right in 4-month-old infants can be selectively reinforced with milk reinforcement, a procedure adapted from Papoušek (1959). Sensitive use of operant procedures has been made by Lipsitt, Pederson, and DeLucia (1966) in a study of year-old children whose rate of response controlled the brightness of a visual display and by Weisberg and Fink (1966) to assess the behavior of 18-month-old children to fixed-ratio schedules of reinforcement. Levison and Levison (1967) and Caron (1967) have used operant head-turn-

ing in studies of the effectiveness of visual displays in controlling the behavior of 3-month-old children. Increasing sophistication and precision in the use of tied-and-true operant procedures in the study of infants hold promise of permitting a more careful assessment of infantile sensory sensitivity, perceptual organization, memory, and motivational variation than has been possible in the past.

The laboratories at Brown University have reported several applications of operant procedures to infants in the first days of life. Lipsitt and Kaye (1965) showed changes over time in amount of sucking to the alternated presentation of a rubber nipple (on which sucking increased) and a straight rubber tube (on which sucking decreased). Increased tube-sucking with reinforcement of dextrose solution has also been reported (Lipsitt, Kaye, and Bosack, 1966). Siqueland and Lipsitt (1966) showed an increase in directional head-turning with the contingent application of dextrose-solution reinforcement in children under 4 days of age. Observations by Klon (1967) suggest that changes in the patterns of sucking bursts may be determined by schedules of feeding reinforcement and Sameroff (1969) has shown that short-term changes can be induced in the patterns of sucking by delivering milk on a component-contingent basis.

The most extensive studies of infantile learning to be reported in English are those of Papoušek (1959, 1961, 1967, 1968). In a procedure which mixes somewhat the classical and operant paradigms, Papoušek reinforced with milk the infant's turning of his head toward right or left on the signal of a sound. Ten trials each day were given to a group of children under observation for several months, each of them went through a cycle of acquisition, extinction, reacquisition, discrimination of buzzer and bell as signals for left or right head-turn, and two reversals of the discrimination of sounds. With a stringent criterion of learning (five consecutive responses to the auditory signal during a 10-trial session), he found that infants who were started in the procedure during the newborn period acquired the conditioned response after 177 trials (near the end of the first month of life). Papoušek (1967) calls attention to the fact that only the extinction pro-

cedure shows no systematic relation to age. He has found (Papoušek, personal communication), as has his colleague Janoš (1965), that gestational age and ease of conditioning are highly correlated. Papoušek has also found remarkable individual variation in rate of conditioning.

The Context of Learning. Even with the spurt of studies of infantile learning that has occurred in the past decade, the number of studies is insufficient to the important questions that can be posed. Nevertheless, a number of tentative general principles and, perhaps of greater importance, a number of critical questions can be stated on the basis of data in hand. The least disputable principle is that age, with whatever process that age reflects or hides, is influential in determining the course of early learning. Procedures of marginal effectiveness in the first weeks of life give notable effects at 3 months. Here again the rate of developmental change puts demands on theories of infancy and on experimental procedures to guarantee that changes shown do not represent general maturational change in sensitivity or response effectiveness rather than learning.

A host of empirical and theoretical issues arise from the distinction that Lipsitt (1963) emphasizes between operant control and operant learning. Many of the studies listed earlier can be seen as involving changes in the rate or occasions of occurrence of a well-established response rather than the acquisition of new responses. The distinction reflected in the classical literature of learning between *habit* and *performance* is relevant as well to interpretation of experimental effects as transient fatigue, adaptation, or habituation. It is significant that so little is known about the persistence of behavioral patterns established naturally or in laboratory settings. Almost no studies have examined infants over a long enough period of time to establish measures of persistence of behavior acquired early in life. Systematic studies of infantile memory over more than a few days are limited to a handful of studies (Burt, 1932, 1937, Janoš, 1965, Levy, 1960, Papoušek, 1967).

Every aspect of the study of babies is related to the issue of *state* or level of arousal, and learning is no exception. Gottlieb and Simner (1966) have noted the close and complex relation between measures of arousal

such as heart rate change and measures commonly used as indicators of learning such as sucking Koch (1968) related ease of conditionability to time since waking and time since feeding The relevance of arousal to interpretations of early learning has been put forcefully by Kion (1967), who suggested that many of the procedural operations used in studies of early learning may be as readily interpreted as changing the state of the baby and thereby changing the likelihood of the response under observation Once more, the developmentally crucial difference between habit and performance must be noted

A significant attempt to reconcile conflicting evidence on early, especially newborn, learning has been made by Sameroff (1969) Following Piaget (1936), Sameroff proposed that classical conditioning can take place only after the response systems relevant to the unconditioned and conditioned stimuli have been organized and differentiated He pointed out also that studies of early learning can be more easily understood if the distinction is maintained between stimuli which provoke defensive or avoiding responses and those which provoke orienting or approach responses (see André-Thomas, 1954, Schrier, 1958, and Sokolov, 1960) Sameroff proposed that conditioning is possible only after congenital defensive responses have been somewhat habituated

Does the baby behave as he should according to the simple paradigms of learning? Papoušek (1968) has given the question empirical import by observing the response of young infants to simple, predictable patterns of stimulation, for example, the signal for a left turn of the infant's head alternates regularly with a signal for a right turn Apparently, in the first months of life, babies adopt what can be called "strategies" for anticipating sequential events Papoušek outlines the theoretical problem and puts the psychology of infant learning on a new path when he says "sometimes, we even had the impression that successful solving of the problem itself elicited more pleasure in the subject than the reward" It is beyond doubt that babies are shaped by their early experience and the exciting task of the next generation of researchers will be to enlarge and complicate the paradigms of learning to make room for the complexity of the infant

The Infant as Perceiver and Thinker

A notable discrepancy exists between the amount of interest currently invested in early cognitive development—the infant as perceiver and thinker—and the amount of research that has been carried out Charlesworth (1968) has observed that the great bulk of research on infantile cognition has taken place since 1960, psychology is truly only at the edge of its study of perception, thinking, problem-solving, dreams, play, and language in the very young child (Kessen, 1966) There are one major and several minor exceptions to the principle of waywardness and lag in the study of early cognition Minor exceptions can be seen in the interest of many investigators around the turn-of-the-century in early language and in the continuing *theoretical* interest of students of perception in the child's first view of his world The major exception, and one that has transformed the study of infants irreversibly, is the work of Jean Piaget

Perception Theoretical controversy over the nature of human perception has long had implication for the psychology of infancy (Hochberg, 1962) The classical issue of whether perception was innately organized (Pastore, 1960) or derived from an increasing sensitivity to critical features of the environment (Gibson, 1969) or constructed from motor acts (Piaget, 1936) clearly calls for an answer from young children Only recently, and in large part as a consequence of the observations of Robert Fantz, have these arguments been subjected to empirical observation of babies The detailed treatment of infantile vision later in the chapter summarizes the evidence now available on early development of visual perception and its implication for the classic controversies about perception

Language Almost at the same time that interest in early perception was revived there appeared a new flurry of studies of early language Although the procedures for gathering data about the child's early speech have been closely akin to those used by investigators of many years ago (Dewey, 1894, Strayer, 1930), recent observations on early language have been illuminated by their connections with linguistic theory and with general theory of cognitive development In a chapter of this *Manual* McNeill presents a

summary and an analysis of what is now known about the acquisition of language

The Special Place of Piaget's Work After his first observations on his eldest daughter, Piaget (1927) concluded that "the first year of the child is still, unhappily, a mysterious abyss for the psychologist" Piaget's willingness to enter the abyss and to begin to unravel some of the mysteries stands as the most important contribution yet made to an understanding of the human infant The study of infancy has been a major and continuing theme in Piaget's work, but his primary observations and most important theoretical postulations about the nature of young children were contained in three books *The Origins of Intelligence in Children* (1936), *The Construction of Reality in Children* (1937), and *Play, Dreams, and Imitation* (1945) His profound and complicated account of infancy, drawn largely from observations on his own three children, does not submit to easy abbreviation here Fortunately, Flavell (1963) and Wolff (1960), among others, have prepared analytic and comparative accounts of Piaget's theory of the infant mind

Piaget sees the infant as actively engaged with his environment On the basis of congenitally organized reflexes—vision, prehension, sucking, and phonation—the child builds ever more complicated ways of dealing with environmental events His adaptation is the result of a shifting balance between understanding the world in terms of his present structures (*assimilation*) and modifying those structures to fit the demands of the environment (*accommodation*) The normal child in the usual environment of infants thereby develops, in a regular sequence, conceptions of space, time, and object which are increasingly like those of the adult Piaget's observational techniques and the conceptual use to which he puts what he sees can be best understood with an example

At 0,2 (4) [age two months and four days] Laurent by chance discovers his right index finger and looks at it briefly At 0,2 (11) he inspects for a moment his open right hand, perceived by chance At 0,2 (14), on the other hand, he looks three times in succession at his left hand and chiefly at his raised index finger At 0,2 (17) he follows its spontaneous

movement for a moment, then examines it several times while it searches for his nose or rubs his eye Next day, same observation At 0,2 (19) he smiles at the same hand after having contemplated it eleven times in succession The same day he looks very attentively at his two clasped hands At 0,2 (21) he holds his two fists in the air and looks at the left one, after which he slowly brings it toward his face and rubs his nose with it, then his eye A moment later the left hand again approaches his face, he looks at it and touches his nose He recommences and laughs five or six times in succession while moving the left hand to his face He seems to laugh before the hand moves, but looking has no influence on its movement At a given moment he turns his head to the left but looking has no effect on the direction At 0,2 (23) he looks at his right hand, then at his clasped hands (at length)

It may thus be seen of what the coordinations between vision and the first circular reactions of the hand and fingers consist We can say that the visual schemata tend to assimilate the manual schemata without the converse being yet true In other words, the glance tries to follow what the hand does, but the hand does not tend in any way to realize what the glance sees, it does not even succeed in remaining in the visual field! Later, on the contrary, the hand will be regulated by vision, and vice versa, this will enable the child to grasp the objects seen But, for the time being, the hand moves independently of the glance, the few vague circular reactions to which it gives rise being only directed by touch, kinesthetic sensations, or sucking The relations between sight and hand movements are therefore different from those which exist between sucking and these movements, in the case of sucking, the schemata external to the hand movements control them and incorporate them (sucking entails circular reaction of the arms and hands) while in the case of vision hand movements are autonomous and the glance is limited to assimilating without controlling them

By means of such combinations of naturalistic observations and contrived intervention, Piaget developed a systematic account of intellectual change over the first months of life

Along the way, he has addressed fundamental issues that have not had a place in American studies of babies—among them, the development of intention, the separation of means and goals, the growing use of instruments in the solving of problems, and the formation of categories of knowledge such as space and object. Piaget's theoretical apparatus is, of course, not universally accepted (Kessen and Kuhlman, 1962) and replication of his observations is essential, both in the mode he preferred and in the more usual style of experimental study. Nonetheless, White (1969) speaks for many students of children when he describes Piaget's *Origins of Intelligence* as "far and away the most outstanding body of work on human infancy."

The Return of Prehension Piaget's emphasis on the development of independent motor systems—for example, looking and grasping—and their subsequent coordination has produced a revival of interest in the study of early patterns of prehension and their relation to looking, sucking, and the development of the notion of permanent objects. Brainard (1927) had noted the changes that take place in the coordination of eye and hand during the first half-year of life. The development of such coordination has been given a neuropsychological definition (Zagora, 1959) and the development of stable handedness in patterns of reaching and manipulation has been assessed longitudinally (Flament, 1965). In a series of studies of infants in an institution, White and his colleagues have carefully charted the normal course of visually directed reaching and have, further, demonstrated that the rate of development can be modified by experimentally introduced stimulation of the children (White, 1968, 1969, White, Castle, and Held, 1964). Bruner has taken the early development of grasping and its coordination with looking and sucking as a model for problem solving in the very young infant (Bruner, 1967, Bruner, Simenson, and Lyons, 1968, Bruner and Watkins, 1968).

Play, Interest, and Attention Piaget's treatment of cognitive development brings into a sharp light the behavior of infants that seems closely related neither to the alleviation of primary drives nor to the actions of a social partner. The principle that children are active explorers of their environment and are pleased by cognitive achievements has been put in

several forms by Berlyne (1960), Hunt (1961), Rheingold, Stanley, and Cooley (1962), Stott (1961), and Wolff (1966). Although empirical work has not kept pace with speculations about the broader base of infantile motivation, several patterns of study have begun to emerge. In addition to Piaget's observations on *play* (1945), Friedlander and Kessler (1968) have described procedures for recording play patterns over long periods of time, and observations on patterns of free play at the Fels Research Institute (Goldberg and Lewis, 1969) and at Haivard (Kagan, personal communication) have begun to present evidence on the developmental stability of patterns of play and on the continuity of individual differences. Charlesworth (1969) has presented a detailed treatment of *surprise* as a factor in early motivation and cognitive development. A number of researchers have called attention to the importance of *complexity* as a variable governing the interest and attention of the young infant (Berlyne, 1960, Brennan, Ames, and Moore, 1966, Charlesworth, 1966, Munsinger and Weil, 1967, Thomas, 1965). *Discrepancy from a familiar pattern* as an influential determinant of attention, an idea elaborated by Sokolov (1960) and given application to early cognitive development by Jeffrey (1967), has been closely analyzed in Kagan's longitudinal study of early development (Kagan and Lewis, 1965, McCall and Kagan, 1968). Evidence also has begun to accumulate on the importance of *arousal* or alertness in studies of attention (Korner and Grobstein, 1966, Stechler, Bradford, and Levy, 1967) and on the existence of puzzling variation in patterns of attention from one child to another (Kagan, personal communication, McCall and Kagan, 1967).

Except for the work of Piaget, the study of the infant as thinker has just begun. Among the promising directions for development are a closer look at memory and time-sense in infants (Allen, 1931, Watson, 1967), the establishment of links between early conditioning and problem-solving (as, for example, in Papoušek's infant strategists) and in the formal treatment of Piaget's theory of early cognitive change (Lau In-Mao, 1961).

The Infant as Social Partner

Psychologists have long been concerned with charting the course the child takes as

he becomes a social being, effective in changing the behavior of others and responsive himself to social partners. From the early observations of Kaila (1932) and Spitz and Wolf (1946), the focus of research on the infant as social partner has been concentrated on the study of smiling and attachment to the care-taking mother. The relevant research has been given close treatment by Maccoby elsewhere in this book, and her discussion will not be duplicated here.

The sixfold division of infancy research used in the foregoing discussion is necessarily abstract and necessarily artificial. There are serious connections among the areas of interest elliptically designated as reflex, emergent, sensory, learning, cognitive, and social. Nonetheless, the division roughly describes variation in research that characterizes the twentieth century and gives some sense of the change from dominant conceptions of the infant as creature of reflexes to conceptions of the infant as influential in determining the nature of his environment.

In the next section of the present report, a shift is made from a general and summary statement of available research to a more highly concentrated treatment of three collections of research—sucking, habituation, and vision—in illustration of the complex interaction of problem statement, method, and findings in the study of infants.

THE CASE OF SUCKING

Sucking as an Organized Biological Behavior

Rooting. The awake, hungry, newborn infant exhibits rapid pendular searching movements in response to tactile stimulation in the region around the mouth (Peiper, 1963, Prechtl, 1958). This pattern of searching movements, called the rooting reflex, is held to optimize the infant's chances of finding and grasping the nipple. Pepys is credited by Peiper with writing in 1667 the first description of rooting that occurred even before the first feeding. Several writers have corroborated the existence of the rooting response in the newborn (Blanton, 1917, Blauvelt, 1964, Gentry and Aldrich, 1948, Peiper, 1963, Turkewitz, Gordon, and Birch, 1965, Watson, 1919, Wolff, 1959), in the fetus (Hooker, 1952), and in the premature infant (Prechtl, 1958, Saint-Anne Dargassies, 1955).

Gentry and Aldrich (1948) and Prechtl (1958) found rooting in about two-thirds of awake full-term babies tested before feeding. Blauvelt and McKenna (1961) have provided a detailed temporal analysis of rooting.

Several investigators have found that the rooting response is affected by state of arousal; the response increases in probability and in vigor as the baby becomes more alert (Peiper, 1963, Prechtl, 1958, Gentry and Aldrich, 1948, Wolff, 1959). Wolff (1959) has argued that state of arousal is a more crucial variable than time since last feeding. Of 48 babies, 46 were reported by him to root when alert even immediately after a meal. The nervous organization of the rooting reflex is most assuredly quite low. It has been shown repeatedly that anencephalics and microcephalics root in patterns much like those of the normal baby (Blanton, 1917, Ingram, 1962, Peiper, 1963, Prechtl, 1958).

Mechanics and Components of Milk Extraction. The newborn infant has three sets of oral pads which are believed to facilitate and support the sucking act (Middlemore, 1941, Peiper, 1963). One set is on the outer and inner aspects of the lips and a second set on the gums; these two sets of pads form a closed-pressure seal around the nipple. A third set of pads on the inside of the cheeks is believed to support the cheeks so they are not sucked in by the negative intraoral pressure established during sucking.

According to Peiper (1963), Erasmus Darwin correctly noted in the eighteenth century that the infant does not sip milk at the breast but, instead, takes the nipple into his mouth and draws milk out by repeatedly pressing the nipple between his gums. Further analysis of the act has shown that sucking is made up of two major components—the establishment of *negative pressure* within the mouth and the lapping or *expressing* of the nipple.

It has been demonstrated that the sucking infant rhythmically establishes a condition of *negative pressure* in his mouth, but there is not a complete consensus as to how this pressure is established and exactly what role it plays in extracting milk from the nipple. Jensen (1932) summarized early work in support of the hypothesis that the infant, like the adult, sucked by establishing negative pressure through inspiration. In contrast, Auerbach (in Jensen, 1932) was the first of

many investigators to maintain that infant and adult use markedly different techniques to establish negative pressure. The adult establishes negative pressure by thoracic inspiration but the infant was said to use "mouth sucking"—a procedure whereby the oral cavity, closed off at the back and sealed by lips and gums at the front, is increased in volume by dropping the lower jaw (Kasahara, 1916). Although Auerbach's view is generally held to be correct (Peiper, 1963), it has not gone unchallenged. Halverson (1944), for example, found costal respiration to predominate over abdominal respiration during vigorous sucking, an observation suggesting thoracic involvement in the infant's sucking act.

The second mechanism used by the infant for extracting milk is called *expressing*. After the nipple is sucked into the mouth, the jaw and curved tongue are raised. The tongue presses the nipple against the hard palate and presses out milk by moving from the front to the back of the mouth. Cinematographic evidence of this process has been provided by Aidran, Kemp, and Lind (1958) and by Lassrich (1959). Aidran, Kemp, and Lind found no evidence that milk was taken in during the phase of negative pressure when the tongue and jaw were dropped. Their evidence suggested that this phase chiefly provided time and negative pressure for refilling the teat. On the other hand, Colley and Creamer (1958) found insignificant pressure changes inside the nipple and argued against the position that the nipple was being pressed against the roof of the mouth. Variation in procedure, particularly in rigidity of nipples used, probably accounts for the discrepancy in observations. Sameroff (1968) obtained convincing evidence that both negative pressure and expressing can be used by newborn infants to extract milk.

Coordination of Sucking, Respiration, and Swallowing. A smooth feeding performance requires coordination of sucking, swallowing, and respiration. Swallowing apparently depends on the amount of milk in the mouth (Halverson, 1938), babies almost never swallow when sucking air (Jensen, 1932). The baby does not visibly interrupt his breathing when swallowing, but it does not follow that he can breathe and swallow simultaneously. Halverson (1944) and Lassrich (1959) found

swallowing to require less than 0.5 seconds for the infant as opposed to 1.5 seconds for the adult (Peiper, 1963). Inasmuch as swallowing occurs in the interval between inspiration and expiration, the effect of swallowing on respiration has often gone undetected.

There is disagreement as to whether or not sucking and respiration are coordinated. Balint (1948) and Colley and Creamer (1958) found no relationship between sucking and breathing but Peiper (1963) and Halverson (1944) found definite relationships of 1:1 or 2:1 sucks to respirations, and several reports of deepened inspiration during sucking have been made (Ribble, 1938, 1943; Halverson, 1941, 1944). Halverson (1944) noted that the pattern of breathing changes during vigorous sucking, costal breathing predominates with sucking bursts often anticipated by abdominal tensing. He concluded that the best coordination of sucking, breathing, and swallowing occurs when a suck is made during an inspiration and a swallow is made between an inspiration and an expiration. Peiper (1931) found that respiration rate slowed during sucking and that both sucking and breathing slowed when the infant was changed from nonnutritive to nutritive sucking. He argued that a hierarchical control of swallowing, sucking, and breathing exists with swallowing controlling sucking and sucking controlling breathing.

Effects of Age. Although most babies suck at birth or before, very little is known about how the mechanics of sucking change over age. Ribble (1939) reported that some premature babies have trouble grasping the nipple and do not suck strongly enough to draw milk from the breast. Halverson (1946) found the coordination of sucking, swallowing, and breathing to be highly variable from one premature baby to another. In his study of infants from birth to 18 weeks, Halverson (1946) found good coordination of sucking, respiration, and swallowing in one baby at 8 hours, in 3 babies in the first 3 days, in 8 others at one time or another, in 2 babies, smooth coordination never appeared during the study. Prechtl (1956) reported that the newborn infant tends to use negative pressure as his chief milk-getting technique, whereas after some weeks the child will tend to use expression. Auerbach wrote (Halverson, 1938) that the infant sucked by downward stroking

of the jaw for the first 4 to 5 months and later used thoracic inspiration. It is noteworthy that Ardian et al. (1958), who studied 41 infants "from a few days to several months" did not report age changes in the form of the sucking response. Bruner (1967) has reported that sometimes at 2 months, but at least by 4 months, a baby presented with a novel stimulus may stop the phase of negative pressure but will continue expressing.

Sucking and Mode of Feeding Ardian et al. (1958) found no essential differences between the baby's technique for sucking breast and his technique for sucking bottle, but Peiper (1963) emphatically insisted that differences exist. Several studies have shown that infants can drink from a cup from birth (e.g., Sears and Wise, 1950), clearly, the specific sucking mechanics described earlier do not provide the only method a baby can use to feed.

Pathology The absence of coordinated sucking, swallowing, and breathing may be indicative of brain trauma or retardation (Blanton, 1917, Kasahara, 1916, Ribble, 1939, Watson, 1919). However, sucking alone is usually intact even with relatively severe trauma (Blanton, 1917, Kasahara, 1916, Peiper, 1963, Ribble, 1937). Peiper (1963) discussed a variety of evidence from human monsters and lower animals that sucking is organized at a relatively primitive level of the nervous system.

Rhythms and Rates of Sucking The infant generally sucks in a more or less regular pattern of bursts and pauses. During bursts of nonnutritive sucking, his rate varies around two sucks a second (Wolff, 1969). Although sucking rate has been reported by many investigators, several important variables are often not specified—age and health of the baby, time since last feeding, state of arousal, whether the baby is sucking for nutriment or on a pacifier, the nature of the nipple, and rate of milk flow. Moreover, several measures of the response can be calculated from the sucking record, for example, sucking rate during sucking, sucking frequency per unit time, duration of a sucking burst, duration of a rest between bursts, and number of sucks per burst. As Balint (1948) and Kaye (1967) have pointed out, experimenters frequently do not make clear whether their rate-of-sucking calculation was obtained by calculating mean

sucking rate during a burst of sucking or by assessing frequency of sucking over a fixed time period. Further, some experimenters have reported ranges for individual subjects and others have reported ranges of group means. Over a wide range of variables it appears that sucking rate during bursts is fairly uniform from 1 to 2.5 sucks per second, close to the value of 1.5 sucks per second reported by Ardian, Kemp and Lind (1959) using cine-mariadiographic analysis. Sucking bursts seem to occur in packages of from about 5 to 24 sucks per burst.

Balint (1948) reported two additional sucking frequencies found in a large portion of his subjects, which were later confirmed by Kaye (1966). A "restart" frequency of from 6 to 10 per second sometimes appeared at the beginning of a sucking burst and a quivering frequency, from 12 to 45 per second, appeared to be caused by tongue or jaw quivering. Neither frequency was related to the infant's age but the quivering appeared in 66% of the females and only 39% of the males, the only substantial sex difference reported for nutritive sucking.

Care has not always been taken to define the parameters separating one burst from another. Investigators attempting to quantify the burst variable have used either a 1-second or 2-second no-sucking interval to define the beginning or end of a burst (Halverson, 1944, Kaye, 1967, Sameroff, 1967). The pause between bursts has been considered to be either a rest period (Halverson, 1944), a play period (Halverson, 1944), or a period during which information is being processed (Bronstein et al., 1958, Bruner, 1967, Haith, 1966, Haith et al., 1969, Keen, 1964, Piaget, 1952).

Variables Affecting Sucking Rate and Rhythm

Hunger Rather strong contradictions exist in the literature regarding the effect of hunger on the various parameters of sucking. Susswein (cited in Peiper, 1963) reported that the baby sucks continuously for the first several minutes of a feeding, then breaks into bursts and pauses as he becomes satiated, an observation confirmed by Norval (1946). Kaye (1966) experimentally confirmed an earlier correlational finding (Levin and Kaye, 1964) that sucking rate changed with amount

of nutrient consumed. But Kion, Stein, and Goddard (1967) observed no change of sucking rate over 9 minutes of feeding. Similarly, Balint (1948) found the rate of sucking to remain constant within $\frac{1}{2}$ sucks per second in over 90% of his sample and the pause-burst pattern to remain essentially constant for 75%. Jensen (1932) reported that 10 of 17 of his subjects sucked air for as long as 15 minutes after a feeding.

Fatigue has been implicated in the depression of sucking rate over time during nonnutritive sucking; full recovery is held to occur after a rest of 60 seconds (Kaye, 1967). However, it is unclear whether or not recovery after a rest reflects the dissipation of fatigue or the response to a change of stimulus. Norval (1946) reported a recovery of sucking rate when the infant was moved from one breast to the other and the positive relationship between arousal and sucking rate has been well documented both observationally (Levin and Kaye, 1964) and experimentally (Bridger, 1962, Jensen, 1932, Kaye, 1966). In fact it can be argued that arousal, not hunger, plays the major role in determining the rate of sucking (Bridger, 1962, Kaye, 1966, Kessen, 1967).

Age. Bronshteyn, Antonova, Kamenetskaya, Luppova, and Sytova (1958) reported that infants over 1 day of age have a higher maximum rate of sucking than infants under 24 hours of age but that pauses and the number of sucks per burst were independent of age. Bruner (1967), however, reported that younger infants pause irregularly, as they grow older, they change to a more regular pattern. Balint (1948) found that babies held fairly closely to their basic sucking frequency over 2 to 2½ months of follow-up study while Kasahara (1916) reported that babies over a week of age do not pause while sucking nutritively, whereas newborns do.

Rate of Milk Flow. Colley and Creamer (1958) and Halverson (1944) found sucking rate and the presence of pauses to be affected by milk flow, possibly through the control that swallowing exerts over sucking. Some of the discrepancies found in the reports of sucking rates and burst patterns might be accounted for by variation in rate of milk flow.

Individual Stability. Infants show a fairly regular rate of responding both within an

experimental session (Haith, 1966, Haith, Kessen, and Collins, 1969, Kion, Ipsen, and Goddard, 1968, Levin and Kaye, 1964, Sameroff, 1967, Wolff, 1969) and over longer periods of time (Balint, 1948).

Natural Cycles of Feeding. A great deal has been written about whether the baby's cyclic demands for nourishment should be met (demand feeding) or whether the baby should be made to adapt to an imposed regular schedule of feeding (scheduled feeding). Frank (1966) noted that the changing advice to mothers from pediatricians and federal publications through the decades from 1900 is an instructive lesson in how the "truth" about infant rearing changes. In a personal communication to Frank, Anton Carlson reported that the 4-hour schedule of feeding apparently originated with a barium X-ray study of 3 newborns in 1900 which showed that the stomach emptied after about 4 hours. The generalization from 3 newborns fed a foreign substance to milk-drinking infants in general is, at best, dubious. The history of the demand-schedule issue has also been reviewed by Weinfeld (1950).

Only a few studies have been carried out on the plasticity of the newborn to an imposed schedule. Both Bystroletova (1954) and Marquis (1941) reported that babies adapted to their feeding schedule during the first 10 days of life. If fed on demand, the newborn baby may require from 10 to 14 feedings a day (Trainham and Montgomery, 1946, Simsarian and McLendon, 1942, 1945) in a more or less irregular pattern but, in a matter of several days or a few weeks, most infants will settle down to a fairly regular pattern of 5 to 6 feedings a day. Aldrich and Hewitt (1947) studied 100 demand-fed babies for over a year to discover their preferred feeding rhythm; their data are shown in Fig. 2. Self-regulating rhythms appear to approximate the commonly prescribed 4-hour interval for many infants.

Scheduled feeding has been justified as necessary to avoid the harmful effects of overeating, especially in the premature infant. However, it has been found that premature infants do well on a demand schedule (Horton, Lubchenko, and Gordon, 1952) and that demand feeding generally results in faster weight gain and earlier release from the

Fig 2 Self-regulating schedule of feeding for 100 infants (From Aldrich and Hewitt, 1947, p 347)

hospital nursery (Hardy and Goldstein, 1951)

Sucking as an Indicator of Underlying Process

The sucking response is one of the few organized responses present at birth and has the several advantages of being relatively easy to define, measure, elicit, and record. Perhaps for these reasons, sucking frequently has been used as an indicator of underlying process in the young infant. Over the years, some aspect of sucking has been called on to assess discrimination, learning, attention, habituation, arousal, and frustration.

Discrimination A number of studies have used the sucking response to measure the sensitivity of the newborn (e.g., Dockeray, 1934; Jensen, 1932). Peiper (1963) reviewed classical evidence that sweet substances provoked sucking movements. Dockeray (1934) reported that some infants consistently responded negatively to acidic formulas. Nelson (Jensen, 1932) observed differential responding to sugar, salt, quinine water, and citric solutions by, respectively, 50, 40, 33, 32, and 23% of infants observed. Jensen (1932) obtained no differential response between sugar and milk and differential but irregular responses to varying concentrations of salt. Bronshtein et al. (1958) reported increased sucking to sugar solutions and decreased sucking to salt solutions. Dockeray (1934) reported no effect of odor on sucking but Bronshtein et al. (1958) found differential responding to three odors. Temperature sensitivity in infants has not been widely studied. Kasahara (1916) reported lower and upper limits of temperature that infants will tolerate to be approximately

30 and 40°C, whereas Jensen (1932) reported values of 19 and 52°C. Reported discrimination of sound intensity and frequency as measured by variation in sucking (Bronshtein et al., 1958) has not been replicated (Keen, 1964), nor have Bronshtein and his co-workers' reports of visual discrimination using similar procedures found support (Haith et al., 1969; Kaye, 1967; Sameroff, 1967).

Learning The discrepancy between the amount and quality of research on newborns and the amount and quality of research on older infants is quite apparent in studies that use the sucking response as a conditioned response or as an indicator of learning. Unfortunately, without systematic observation of changes across age in the acquisition and extinction of learned responses, it is often difficult to interpret experimental findings. The presence of differences between treated and untreated samples of the same age invites many interpretations, particularly when only a small number of trials are presented, when all of the training takes place in a single session, or when appropriate control groups are absent. Long-term developmental studies of sucking as a learned response, comparable to the work of Papoušek (1967) on head-turning, are rare, and the results of many available studies can be understood as representing transient changes in adaptation or arousal.

Developmental Studies Ripin (1930), studying the sucking responses anticipatory to feeding in babies during the first half-year of life, found occasional anticipatory responses as early as 1 month, but she concluded after examining changes in behavior over 6 months that true expectancies were not established.

until the third month of life Kasatkin (1952) and Dashkovskaya (1953) described "unstable" conditioning in the first days of life, but "stable" conditioning appeared only after the newborn period

Naturalistic Observations of Learning Several studies have deviated from customary learning paradigms to study infant learning in relatively natural circumstances A single infant, reportedly a newborn traumatized at the breast by partial suffocation, subsequently "fought" the mother during the feeding situation (Gunther, 1961) Call (1964) reported film-documented cases of newborn infants who moved their heads from side to side and grasped the mother's breast when placed in the feeding position The adjustment of activity patterns in newborn infants fed at different intervals has been observed (Marquis, 1943, Bystroletova, 1954) Thompson (1926) reported that an infant could learn to feed from a poorly shaped nipple by a "fading" procedure using a breast shield When newborn infants repeatedly have a nipple inserted in their mouths and then withdrawn, they tend to quiet faster on insertion and cry sooner on withdrawal during late trials (Cohen, 1966)

Short-Term Laboratory Studies Along more conventional lines, Marquis (1931) reported conditioning of mouth opening and the cessation of activity and crying after repeated pairings of buzzer and milk bottle Dashkovskaya (1953), using sound stimulation as a conditioned stimulus, reported a confirmation of these findings with newborns, but she was not able to establish conditioning to a light conditioned stimulus Sameroff (1968) observed the effects of differential milk reinforcement on the two major components of sucking He found a lowered amplitude of the suctioning component when the expressing component was reinforced In a second experiment he demonstrated that the magnitude of the expressing component, after brief practice by the baby, roughly matched the effort necessary to obtain milk

Lipsitt and his colleagues at Brown University have carried out a number of studies of the conditioning of sucking in newborns In one study (Lipsitt and Kaye, 1964) in which tone and nipple-induced sucking were paired, they found greater mouthing to the tone in experimental than in control babies

but only during the extinction phase In a second study, Lipsitt and Kaye (1965) found more nipple-sucking in groups which received opportunity to suck nipple and tube, in an alternating schedule, than in a group receiving opportunity to suck only the nipple In still a third study, sucking frequency on a tube by babies who received dextrose during tube presentation was compared with sucking frequency by babies who received dextrose through a syringe 20 seconds after withdrawal of the tube (Lipsitt et al, 1966) During test trials, tube-dextrose babies gave more mouthing responses than did tube-alone babies

The results of these studies, taken together, have been considered to constitute evidence for learning in the suckling infant However, even in the most carefully executed and adequately controlled experiments on learning in the literature of infantile sucking, the possibility remains that experimental manipulations may have systematically influenced arousal in favor of the experimental groups There can be no doubt that sucking behavior changes in response to environmental change during the first days of life, what remains in doubt is a conclusion about the most productive explanation to put on the facts Two recent proposals (Kron, 1968, Sameroff, 1969) that go beyond the limited and limiting issue of whether or not the newborn infant can learn (Kessen, 1963, Lipsitt, 1966) were discussed earlier

Attention, the Orienting Response, and Sucking One of the best-known correlates of attention and of the orienting response is inhibition of ongoing activity (Berlyne, 1960, Sokolov, 1963) Observations on inhibition of sucking during visual exploration were, in fact, made by Piaget (1936) and by Fleischl (1957) Studying infants from birth to several months of age, Bronshtein et al (1958) reported inhibition of sucking to visual and to auditory stimuli and, further, an attenuation of the tendency to inhibit sucking as stimuli were repeatedly presented However, for the most part, the "Bronshtein effect" has been difficult to replicate Some of the difficulties in replication probably derive from the vague description of procedures, stimuli, and age range in the original report For example, most of the attempts at replication in the United States have been carried out with newborns on non-nutritive sucking Brackbill (1962) reported after visiting Russian laboratories that full

manifestation of inhibition, habituation, and subsequent dishabituation of *nutritive* sucking to a visual stimulus could be demonstrated in only one-third of the babies between a few hours and 17 days of age

Kaye and Levin (1963) attempted to replicate the Bronshten effect in two independent studies but could not find even initial inhibition of sucking. Additional studies by Kaye (1967) have produced similar requests. Keen (1964) found differential changes in sucking during presentation of tone for two durations, but the absence of no-tone observations makes it difficult to determine whether these differences reflected relative facilitation or relative inhibition of the response. Haith (1964) reported that suppression of newborn sucking was stronger to a light moving intermittently than to stationary light. In contrast to prior studies, Haith made the nipple available to infants only during discrete trials. Kaye (1967) reported studies of audition in which a similar procedure was used but he found no stable differences in performance attributable to tone. Under somewhat different procedures, Kaye (1967) was also unsuccessful in his attempt to replicate the Haith study with visual stimuli. Samei-off (1967) presented light, tone, and light and tone to newborns and found no effect on time spent sucking. However, he did find that the number of sucking bursts was fewer during all experimental presentations than during any control interval. Using 2- to 4-month-old infants, Haith, Kessen, and Collins (1969, and Collins, Kessen, and Haith, personal communication) found inhibition of sucking to both stimulus movement and to flashing lights but no stable relation was found between sucking inhibition and stimulus complexity. Moreover, there was no evidence of habituation of sucking inhibition with repeated stimulus presentation.

Sucking without Nutrient

In addition to its obvious contribution to efficient feeding, sucking is significant in other aspects of the infant's life. Commentators working from both observation and clever speculation have, moreover, assigned critical theoretical weight to sucking, especially sucking that does not produce nutrient. In fact, a great deal of research and speculation about sucking in infancy has hinged on the simple fact that infants suck on fingers, thumbs,

sleeves, toys, pacifiers, and other objects vigorously and for long periods of time without resulting nutritive intake.

In their attempts to account for such behavior, theorists have put forth a surprisingly varied set of arguments. According to some observers, nonnutritive sucking satisfies a "need" to suck; it serves to "pacify" the infant during moments of distress; it serves as one of a number of responses to dissipate a build-up of freely displaceable energy; it becomes positively reinforcing through its association with food; it acquires an erotogenic quality through its association with mother's breast and food; it is a prewired species-specific response to high arousal; it is a species-specific response which serves to attach the mother to her offspring; or, because the oral region is invested with a rich network of nerves and blood vessels, nonnutritive sucking occurs because it feels good.

A number of review papers and theoretical articles have dealt with available research and the theoretical issues involved in the study of nonnutritive sucking (Honzik and McKee, 1962; Kessen and Mandler, 1961; Orlansky, 1949; Palermo, 1956; Ross, Fisher, and King, 1957). The next paragraphs will deal first with the normative aspects of nonnutritive sucking, then with research relevant to the question of whether or not an inborn "need" to suck exists, and, finally, with evidence bearing on the power of sucking to pacify or calm the infant.

Normative Data. Ribble (1943) reported that 60% of 600 infants observed had to be "taught" to suck by moving the infant's jaw up and down over the mother's breast. Her assertion has not been confirmed and is clearly contradicted by a vast amount of literature. A number of investigators have reported finger sucking and hand-mouth contact shortly after birth and even before the first feeding (Blanton, 1917; Blauvelt, 1964; Kessen, Williams, and Williams, 1961; Ripin, 1930; Watson, 1919). Dramatic photographic documentation of the fetus' ability to suck its thumb was recently displayed in a national magazine (*Life*, April 1965).

The reported incidence of nonnutritive sucking among infants has ranged from 44% (Heering, 1932) to 100% (Kunst, 1948). Brazelton (1956) reported that 90% of the infants he observed engaged in nonnutritive

thumbsuckers

	n	Percentage of Thumb- suckers	Onset		Termination								
			3 mos	6 mos	9 mos	12 mos							
							1	2	3	4	5	6	7
Brazelton (1956)	70	87%	100%	100%	74%	93%	93%						
Davis (1940)	150		33		No report but some → 15 yrs

sucking Kunst and Brazelton counted any kind of hand sucking—of finger, first, or thumb—in their estimates, whereas other investigators reporting an incidence of from 44 to 64% (Heering, 1932, Traisman and Traisman, 1958, Yarrow, 1954) apparently counted only sucking of the thumb. Table 5 presents a synopsis of data on onset and termination of nonnutritive sucking.

Investigators have not reported dates of termination of hand-sucking as thoroughly as onset. Brazelton (1956) reported that 74% of his subjects by 9 months and 93% by 12 months had discontinued the habit except when tired, hungry, or unhappy, but the dates of termination of all sucking were not reported. Most investigators have apparently concentrated on all hand-sucking regardless of state. Traisman and Traisman (1958) found that the mean age of termination was approximately 3.8 years. Yarrow (1954) found that half of his subjects had stopped sucking by 4 years. Lewis (1937) reported that 70% of his 30 cases stopped before 6 years. Although thumbsucking persists past 6 years in only a small percentage of subjects, Yarrow reported 14% of the babies he saw who thumb-sucked had not stopped by 7 years of age and several investigators have reported that a small percentage of children persist until adolescence (Davis, 1940, Honzik and McKee, 1962, Swinehart, 1938).

The specific correlates of thumb-sucking are not well known. As the infant grows older the incidence of thumb-sucking becomes associated with particular states. As common experience would suggest, Brazelton (1956)

found that although thumb-sucking disappeared as a common activity for the infant at approximately 12 months, the response continued to appear under conditions of distress. Kunst (1948) found a positive relationship between hunger and tendency to suck. Moreover, infants sucked primarily when they were awake until 17 to 19 weeks of age but then a reversal occurred, with infants sucking more during sleep until 1 year of age. Kunst also observed more sucking in bed than out, a finding she attributed to boredom but which might just as well be attributed to a drowsy state.

Honzik and McKee (1962) have summarized the literature regarding sex differences in thumbsucking. Gesell and Ilg (1937) reported that males sucked more than females but the basis for their statement is unclear. Honzik and McKee presented data from three studies to support their argument for a greater tendency of females to suck, a tendency which they attribute to greater tactile sensitivity. However, a number of studies have not confirmed this finding (Davis, 1940, Kunst, 1948, Traisman and Traisman, 1958) and there is some slight suggestion that Gesell and Ilg's original thesis is correct.

The Need to Suck. The occurrence of non-nutritive sucking has been variously held to reflect a primary drive or need to suck (Levy, 1937, Ribble, 1943), a derived or secondary drive to suck (Sears and Wise, 1950), the presence of an acquired secondary reinforcing property of stimulation produced by sucking (Palermo, 1956), the presence of autoerotic impulses within the child (Freud, 1905) or

the presence of some unfulfilled need which the mother should attempt to rectify

Palermo (1956) pointed out that three forces shaped modern thought to regard thumb-sucking as unhealthy and unnatural, a view which is, to some extent, now on the decline. First, the discovery of the germ and the accompanying hygienic revolution led to the reasonable belief that only clean objects should be permitted to enter the mouth, second, orthodontists (Lewis, 1930, 1937, Swinehart, 1938) reported evidence suggesting that thumb-sucking resulted in malocclusion and jaw deformation, finally, and by far most influentially, Freud's writings were interpreted to mean that a thumb-sucking child was manifesting his autoerotic needs and impulses, engaging in a primitive form of masturbation (Freud, 1905)

Levy is credited with the first attempt to make an empirical study of the etiologic factors involved in the development of persistent thumb-sucking (Levy, 1920). From interviews with over 60 mothers, he concluded that thumb-suckers had fewer feedings per day, were more likely to be on schedule as opposed to demand feeding, and were less likely to have pacifiers. In a later publication Levy (1937) commented that he could always relate the amount of thumb-sucking to the amount of sucking deprivation the child had experienced. Levy and many investigators have taken these findings as demonstration of an inborn primary need of the infant to suck, an important correlate of which is the intake of milk. Ribble (1943), for example, concluded that infants need 2 hours of sucking activity each day until they are 4 months of age. If they receive less opportunity they will suck their fingers.

The Levy-Ribble position on the fundamental need to suck was often taken to represent the view of psychoanalysis (McKee and Honzik, 1962) in spite of Freud's assertion "that the stimulus from the warm stream of milk was really the cause of the pleasurable sensation. To be sure, the gratification of the erogenous zone was at first united with the gratification of the need for nourishment." Whatever the logic of the argument the contrast between innate need and acquired-drive interpretations of nonnutritive sucking has served as a springboard for the confrontation

of psychoanalytic and learning theories of behavior.

Roberts (1944), from interview data, concluded that thumb-suckers fed for substantially shorter periods than did nonthumb-suckers. Roberts also reported that the onset of thumb-sucking often followed shortly on a sharp decrease in feeding time. Many studies have not confirmed the Levy-Roberts findings. A number of retrospective studies have found more thumb-sucking in children who, because of late weaning or longer feedings, had greater access to sucking opportunity than those who had less opportunity (Bernstein, 1955, Sears and Wise, 1950, Yarrow, 1954). Yarrow, for example, found more severe and longer thumb-sucking in a late-weaned as opposed to an early-weaned group. In their large-scale study which involved repeated current interviews with mothers, Traisman and Traisman (1958) found an indefinite relationship between speed of feeding and percentage of babies who thumb-sucked. If nonnutritive sucking is an inverse function of degree of opportunity for nutritive sucking, one would suspect that demand-fed babies would not be thumb-suckers. This prediction has not been confirmed by the available reports (Simsarian, 1947, Traisham and Montgomery, 1946).

Blau and Blau (1955) observed one infant between 3 and 7 weeks of age for about 20 hours a day. The infant was given alternating fast and slow feedings (nipples with many or few holes). Contrary to a need-for-sucking hypothesis, fast feedings were followed by less crying, less nonnutritive sucking, and less activity in the 10-minute period following feeding. Brodbeck (1950) reported stronger sucking to a finger test by newborn babies fed from a small-hole nipple than by babies fed from a large-hole nipple before, after, and between regular 4-hour feedings.

It is possible to feed infants from a cup soon after birth with no detrimental effect on weight gain (Fredeen, 1948). One would suspect from a need-to-suck hypothesis that these infants would engage in more nonnutritive sucking than infants fed by bottle or breast. However, from a learning-theory position, from a strict interpretation of Freud, and from Piaget's statements about reflex extension, the prediction would be made that stronger and more nonnutritive sucking would occur in children who suck nutritively. Brod-

beck (1950) fed one group of babies from a bottle for 4 days and then from a cup for 4 days and compared their sucking strength before, after, and between feedings with a group of babies fed routinely by bottle for 8 days. The first group showed a decrease in sucking strength after a switch to cup-feeding, whereas the bottle-fed group continued strong. Davis, Sears, Miller, and Brodbeck (1948) studied the response of three groups of infants for the first 10 days of life to a sucking test. The babies were bottle-, cup-, or breast-fed. There was a significant increasing trend in sucking responsiveness over days for the breast-fed group only, the trends for cup-fed and bottle-fed groups over days were flat. No differences were found between the groups in general body motility or in crying between feedings. These data were taken as evidence against the Levy-Ribble hypothesis.

Interest in the etiology of thumb-sucking has waned since the 1950s, perhaps as parental concern with thumb-sucking has changed. But the problem of comprehension has not gone away, the data do not allow a strong statement about the causes of nonnutritive sucking in the species or of variation among babies in amount and topography of sucking.

Pacification. The comforting effects of sucking, whether of thumb, fist, or nipple, are relatively well known. Pacifiers are frequently, if reluctantly, used by mothers for the purpose of quieting distressed babies. Although the sucking-quieting effect is well known, little experimental research has been addressed to the antecedents of this relationship or to the mechanism of its operation. The crying and thrashing infant will fairly abruptly cease crying and moving when a pacifier is placed into his mouth, only to begin again when the nipple is removed. The duration of the crying after the nipple is placed into the mouth and the latency to cry after it is removed depends on the degree of hunger and on the baby's familiarity with the nipple (Cohen, 1967, Marquis, 1943). Nurses often mollify newborns with sugar-soaked cotton pacifiers during circumcision. A similar procedure is used in the ritual circumcision of males by Jews where the baby sucks on wine-soaked cotton. Cohen (unpublished) recorded heart rate during circumcision and found little change in the rate or form of the heart record

among infants who sucked on a pacifier. Infants who did not suck, however, showed violent tachycardia and diastolic changes in the form of the electrocardiogram. Wolowick (cited in Peiper, 1963) found an increase in the infant's threshold to shock during sucking and Buns, Blank, and Bridger (1966) found less response to cold-stress during sucking. The occurrence of sucking inhibits activity and reduces level of arousal.

Kessen and his colleagues have regarded limb movement as an indication of infant distress, although it has not been assumed that limb movement *only* reflects distress. Kessen and Leutendorff (1963) found the quieting phenomenon not to be a general property of tactile stimulation alone. Limb activity was dramatically reduced in the stimulation period only during sucking opportunity and recovered rapidly when the nipple was withdrawn. It is possible that the soothing effect of a pacifier derives from the association of the sucking act with nutritive reinforcement, an hypothesis set forth by Palermo (1956). Kessen, Leutendorff, and Stoutsenberger (1967) observed infants 1, 2, and 3 days of age. Of the 50 infants studied, 30 were seen on the first day of life both before and after the first feeding. The quieting-when-sucking phenomenon was observed in babies *before* the first feeding, that is, the pacifying effects of sucking do not depend on association with food.

Kessen and Mandler (1961) have argued, from a variety of evidence, that the running off of an organized behavioral act inhibits anxiety and resulting distress. They hypothesized that the congenitally organized response sequence of sucking relieves distress, quieting the infant, and that nutriment, whose physiological effects require relatively long periods of time, may become positively reinforcing through association with sucking and not the other way around. Bridger (1962) also has argued that specific drives, for example, for food, are not present at birth, and that sucking is a species-specific response to high arousal level.

Rovee and Levin (1966) have challenged the universality of the sucking-quieting relationship. In the Kessen and Leutendorff (1963) and Kessen et al (1967) studies, infants were moderately aroused by diapering before observation but they were usually not

crying Rovee and Levin studied the relationship between initial arousal level and tendency to quiet when given an opportunity to suck. They found that very active babies decreased in activity when presented with the nipple, moderately active babies did not change activity level, and very quiet babies increased in activity when presented with the nipple. They replicated the Kessen et al. finding of an inverse relationship between sucking frequency and amount of activity decrement. There was also a high inverse correlation between time-to-accept nipple and baseline activity. Since an earlier study by Kaye and Levin (1964) had shown a strong inverse relationship between nipple-in time and arousal, apparently the very quiet babies were asleep and were awakened by the lip-stroking procedure used to facilitate nipple acceptance. Clearly, distress cannot be inhibited if it is not present.

There remain questions about the mechanisms involved in the sucking-quieting phenomenon. Halverson (1938) noted an increase in muscle tension during and sometimes before a sucking burst. Further, if sucking behavior pacifies the aroused infant, one might expect to see infants sucking on their own thumbs and fists with a resulting decrement in activity. Wolff (1959, 1966) reported that spontaneous hand-mouth contacts in newborns tended to reduce crying but only before a meal. Hand-mouth contact also reduced the probability of spontaneous startles. Wolff used this evidence to argue that the sucking act discharges freely displaceable energy, which is constantly being generated in the infant. However, Williams and Kessen (1961) found no stable relation between hand-mouth activity and overall limb activity in newborns.

Virtually no experimental work has been carried out to study the relationships between activity and sucking in infants over a few days of age. Access to a pacifier has been suggested for restless infants (Ribble, 1943) and has been found to be helpful for treating "colicky" infants (Levine and Bell, 1950). Kunst (1948) noted that, until about 5 months of age, infants suck on their thumbs more while awake than asleep; after 5 months, a reversal in the pattern occurs. Infants sucked more when hungry and more in bed than out.

From what little evidence and casual observation is available, it appears that non-

nutritive sucking may play different roles for the newborn and for the older infant. The newborn sucks most when highly aroused and is, in general, soothed through the sucking act. In the older infant, thumbsucking seems, except for the hunger drive, to occur most frequently when the infant is in a low state of arousal.

The literature on sucking is vast and various; the iterated concern of child psychologists confirms the assertion of Piaget (1937) that the first changes in sucking are "the beginning of psychology."

THE CASE OF HABITUATION

The newborn infant enters the world with a number of built-in reactions to stimuli. Abrupt stimulation of the neck muscles elicits a Moro reflex, tactile stimulation at the side of the mouth of a hungry infant elicits a rooting reflex, a bright flash of light elicits eye-clamping, a sharp sound elicits tightening of the eyelids. It is obvious to the student of children that these responses change over age; responses are elaborated, modified, and, in the case of many newborn reflexes, often deleted from the child's behavioral repertory. Much infant research in the past has concentrated on acquisition of new responses and on the refinement and recombination of old responses as the child grows. Only recently have child psychologists placed heavy emphasis on changes in the strength of unlearned responses with experience, particularly on the changing power of stimuli to alert or excite the child.

Current theoretical and empirical work on alerting characteristics of stimuli, for both children and adults, grows from a revived interest in *attention* and in *habituation of attention*. The behavior of dogs in Pavlov's laboratory when presented with a novel stimulus—stiffening of the ears, inhibition of ongoing behavior, and other signs of vigilance—led Pavlov (1927) to postulate an unconditioned orienting reflex, the "what is it?" response. The observed pattern of behavior appears to optimize further reception of the stimulus; the attention of the organism is fully directed toward the novel event and he is better able to evaluate its significance. However, taken by itself, the observation that a stimulus change regularly elicits attention and

orientation carries with it rather disturbing implications. Although initial orientation and attention to a stimulus may be biologically useful, continued alerting to a stimulus that has no significance for the organism would make him a victim of irrelevant environmental variability. The problem becomes vivid when one considers the limitless variety of stimuli arriving at the infant's receptors.

Psychologists have generally considered selective *increasing* of attention (e.g., positive conditioning) to be the basic mechanism of selective attention. The mother's face is selected out of the myriad of visual stimuli and increased in salience because of its importance in the biological economy of the child. Recent research, however, has challenged the notion that nonsignificant stimuli which occur regularly are simply unattended; instead, it is argued that the organism actively ignores or filters stimuli which are of no use to him. Thus the emerging picture is one of an infant who gives high priority to novel events. If they are significant, he continues to attend; if not, he habituates.

An Example of Habituation and Some Definitions

Sharpless and Jasper (1956) carried out a fundamental study of habituation of the arousal reaction in the cat. Tones were repeatedly presented to sleeping cats while the investigators monitored brain activity by implanted electrodes. The response to the first presentation of a 500 Hz tone consisted of desynchronization of the brain-wave pattern (lower voltage and increased wave frequency) for as long as 3 minutes. The same tone was presented repeatedly and, with repetition of the stimulus, desynchronization lasted for shorter and shorter periods. However, when a new stimulus was presented (e.g., a 100 Hz or 1000 Hz tone) brain-wave desynchronization immediately reappeared. In this manner, Sharpless and Jasper demonstrated that habituation occurred specifically to the 500-cycle tone presented repeatedly and they eliminated, with appropriate controls, the possibility that the animal had gone into a deeper sleep or that the ear had in some way fatigued. Although Sharpless and Jasper did not find dishabituation to the familiar (i.e., repeated) stimulus after response to the novel stimulus (Pavlov's "dishabituation"), they did find some

recovery of desynchronization. However, if they permitted the activating effects of the novel stimulus to wear off completely, no response to the habituated stimulus was found. Apparently the effect of the novel stimulus was simply to activate the animal, essentially putting him in a different state during the presentation of the familiar stimulus. Habituation has, of course, been studied in other animals and in adult human beings (see, especially, Sokolov, 1960) but the Sharpless and Jasper study can be taken as representative in considering attempts to define habituation.

Conventional learning phenomena and habituation share a common characteristic in that the behavior of the animal changes with exposure to the stimulus. They differ in that learning typically consists of the acquisition of a new response or a change in the control of an old response, whereas habituation consists of the weakening of an unlearned response to stimulation. Whether or not habituation is a kind of learning can be argued; many investigators of infancy have considered it so (Bartoshuk, 1962; Engen and Lipsitt, 1965; Fantz, 1964). Thorpe (1956) has treated habituation as a kind of learning and he described both phenomena as examples of adaptation by the organism. In Thorpe's words, "habituation can be defined as a relatively permanent waning of a response as the result of repeated stimulation which is not followed by any kind of reinforcement [It is] a simple learning not to respond to stimuli which tend to be without significance in the life of the animal."

Thompson and Spenser (1966) also regarded habituation as a kind of learning and emphasized that the response which is habituated is itself unlearned. They note that most investigators have considered habituation to be a response decrement which cannot be attributed either to simple response adaptation or to effector fatigue. Thompson and Spenser have proposed the most specific definition of habituation available, a definition which they presented as a list of nine essential characteristics of the phenomenon.

Given that a particular stimulus elicits a response, repeated applications of the stimulus result in a decreased response. If the stimulus is withheld, the response tends to recover over time. If repeated series of

habituation training and spontaneous recovery are given, habituation becomes successively more rapid. Other things being equal, the more rapid the frequency of stimulation, the more rapid is habituation. The weaker the stimulus, the more rapid is habituation. Strong stimuli may yield no significant habituation. The effects of habituation training may proceed beyond a zero asymptotic response level. Habituation of response to a given stimulus exhibits stimulus generalization to other stimuli. Presentation of another (usually strong) stimulus results in recovery of the habituated response.

Significance of Habituation in Infants

Investigators have seen the study of habituation as significant for probing a variety of seemingly unrelated processes. Studies of attention, memory, model development, discrimination, and learning are cases in point.

Habituation promises to be a useful tool for the study of memory. Clearly, if an infant responds differently to stimulus *X* on trial 10 from the way he behaved on trial 1, state factors controlled, he has "remembered" stimulus *X*. Excitement about the phenomenon of habituation has been generated by an interest in knowing what the information storage capacities of the young infant are and how they develop (Fantz, 1964, Lewis, Bartels, Fadel, and Campbell, 1966, Pancratz and Cohen, 1968). Sokolov (1960), in a theory not unlike Hebb's (1949), has been most explicit about the form of memory implied by selective habituation. He proposed that a "neuronal model" preserves information about the *intensity, quality, duration, and order of presentation* of stimuli. This model or schema becomes more specific with each repetition of the stimulus. Each stimulus later in the series is then compared to the model. If the input coincides with the representation in memory, the stimulus is "recognized" and no orienting response is given. If, however, a mismatch between model and input occurs, the input disconfirms the organism's expectancy and an orienting response is elicited. A slight extension of Sokolov's proposal brings us close to studies of attention in infants (see, especially, Jeffrey, 1968). Several investigators (Berlyne, 1960, Dember and Earl, 1957, Finley, 1967, Haith et al., 1969, McCall and Kagan, 1967) have suggested that discrepancy

or disconfirmation of an expectancy, rather than novelty strictly or complexity, is the most relevant consideration in infantile attention. In Sokolov's terms, it is the mismatch between the neuronal model—the schema or expectancy—and the input which is critical because of the baby's attempt to fit the input to the model. By this reasoning, an input too discrepant from any of the baby's models might not be attended because it cannot be related to any available expectancy. If one adds to this notion Berlyne's (1960) proposition that discrepancy produces arousal which the infant tries to reduce, it follows that an infant will be excited by slight discrepancies from expectancy, will examine the perturbing event, and will thereby reduce the effective uncertainty of the stimulus. In this way, the models or schemas of the baby become increasingly more complicated (Berlyne, 1960, Munsinger and Kessen, 1964, Piaget, 1936). There is a suggestion that moderate as opposed to large or small discrepancies from habituated stimuli elicit greater attention in the infant (Cohen, 1968, Finley, 1967, Kagan, personal communication, McCall and Kagan, 1967). If discrepancy from a model has motivating effects, the habituation paradigm may serve as an important tool for studying the development of such models.

An additional significant implication of selective habituation is the evidence it provides that an infant is able to discriminate two stimuli (Kessen, 1963). Although any study which uses a so-called "novel" stimulus to demonstrate the selectivity of habituation to a familiar stimulus does, in effect, establish the discriminability of the two events, studies which have specifically used habituation as a tool for studying infantile discrimination have been carried out with variation in auditory stimuli (Bridger, 1961, Bronshteyn et al., 1958), auditory localization (Leventhal and Lipsitt, 1964), visual stimuli (Bronshteyn et al., 1958, Saayman, Ames, and Moffett, 1964), vibration, pressure, and olfactory stimuli (Bronshteyn, et al., 1958).

Habituation has also been of significance because of its relation to learning. As noted earlier, the typical argument has been that habituation represents learning not to respond to certain stimuli. Since habituation may predate positive learning in that it does not require the occurrence of a new response,

habituation may provide an index of early learning that avoids the troublesome problem that ease of response elicitation is often confounded with age

Variables under Study in Habituation Research

A large number of studies document the decrease in infantile responding with repeated stimulation. The studies have differed widely in the modality studied, the parameter of stimulation varied, and the responses used. Response decrement has also been examined in its connections with nervous system functioning, age, sex, and state. After a brief survey of such studies, substantial questions of interpretation—in particular, the criteria which warrant the conclusion that response decrement in fact represents habituation—will be addressed.

Sensory Modality Studies of habituation have been carried out in virtually every sensory modality, however, auditory stimuli have been by far the most popular. Investigations of the newborn have employed pure-tone stimuli (Bridger, 1961, Bronshtein et al, 1958, Keen, 1964), modulated pure tones (Eisenberg, Coursin, and Rupp, 1966), pulsed auditory stimuli (Barnet and Goodwin, 1965, Bartoshuk, 1962, 1964, Clifton, 1968, Keen, Chase, and Graham, 1965, Leventhal and Lipsitt, 1964), modulated pulsed stimuli (Bartoshuk, 1964) and complex sounds (Bronshtein et al, 1958, Eisenberg, Griffin, Coursin, and Hunter, 1964). But, on older infants, only two studies of habituation to auditory stimuli have been reported. Pure tones were used by Bronshtein et al, (1958) and Kagan and Lewis, (1965). Music and voices were used by Kagan and Lewis (1965). Habituation to the location of auditory stimulation has also been studied only in the newborn (Bridger, 1968, Leventhal and Lipsitt, 1964).

Habituation studies using olfactory stimuli have been run almost exclusively with newborns (Bronshtein et al, 1958, Engen and Lipsitt, 1965, Engen et al, 1963, Kussmaul, 1896). Studies on the response to repeated presentations of an air jet, presumably a tactile stimulus, have been carried out by Bridger (1961) and by Stechler (1966) on newborns and by Bronshtein et al (1958) on both newborns and older infants. Habituation of response to temperature stimuli

has been reported by Bronshtein et al (1958).

In the visual mode, the responses to repeated presentations of light onset was studied by Bronshtein et al (1958), Peiper (1925), and Pratt (1934) on newborns and by Bronshtein et al (1958), Cohen (1968), Kagan and Lewis (1965), and Lewis et al (1966) in older infants. Repeated presentations of visual stimulus movement have been used in both studies of the newborn (Haith, 1966) and in studies of older infants (Cohen, 1968, Haith et al, 1968, Kagan and Lewis, 1965, Lewis, et al, 1966). No one has reported changes in responsiveness of newborns to repeated presentations of pictures or real objects. However, for older infants, the stimuli of choice for habituation studies have been stationary visual pictures. Investigators have used geometric forms (Kagan and Lewis, 1965, McCall and Kagan, 1967, Pancratz and Cohen, 1968, Saayman et al, 1964), pictures of real objects, faces, or toys (Fantz, 1964, Kagan and Lewis, 1965, Meyers and Cantor, 1966, 1967) or real faces (Charlesworth, 1966).

Parameters of Stimulation The habituation phenomenon has been used to study the rapidity with which a child reaches a stable low level of response as a function of a variety of stimulus parameters. The dimension of stimulus complexity has been studied with flashing or moving lights varying in predictability of shift in location (Cohen, 1968, Haith et al, 1969, Kagan and Lewis, 1965). Investigators have examined rate of habituation as a function of stimulus duration (Bridger, 1961, Clifton et al, 1968, Keen, 1964, Keen et al, 1965), interstimulus interval (Bartoshuk, 1962, 1964, Bridger, 1961, Keen, 1964, Pratt, 1934a, 1934b), and the interval between familiarization and test (Pancratz and Cohen, 1968). Oddly, with few exceptions (Barnet and Goodwin, 1965, Bronshtein et al, 1958, Engen et al, 1963) the effect of stimulus intensity on habituation rate has not been extensively studied. Finally, Charlesworth (1966) studied the effect of predictability of the spatial location in which a face would appear on persistence of a child in playing a game.

Responses Although the primary measure used in habituation studies of animals and adults is desynchronization of the EEG pat-

tern, no studies using this measure on infants have been reported. Barnett and Goodwin (1965) found no habituation of the evoked potential with repeated presentations of click stimuli. Heart rate change or latency to peak heart rate change has been used as the response in a number of studies (Barnett and Goodwin, 1965; Bartoshuk, 1962, 1964; Bridger, 1961; Canestrini, 1913; Clifton, 1968; Eisenberg et al., 1966; Engen et al., 1963; Kagan and Lewis, 1965; Keen et al., 1965; McCall and Kagan, 1967; Meyers and Cantor, 1966, 1967). Among the remaining physiological measures which have been used are respiration (Canestrini, 1913; Engen and Lipsitt, 1965; Engen et al., 1963; Keen et al., 1965; Leventhal and Lipsitt, 1964; Peiper, 1963), galvanic skin response (Jones, 1930), and galvanic skin potential (Stechler, 1966).

The cochleopalpebral response was reportedly used by Moldenhauer in 1881 (Peiper, 1963) and more recently was used by Eisenberg et al. (1964). Behavioral startle or components of the startle response have been used in a number of studies of newborn habituation (Barnett and Goodwin, 1965; Bridger, 1961; Eisenberg et al., 1966; Eisenberg et al., 1964; Peiper, 1925, 1963). Total fixation time, number of looks, and duration of first fixation were measures in studies using single visual stimulus presentations (Cohen, 1968; Kagan and Lewis, 1965; Lewis et al., 1966; McCall and Kagan, 1967; Meyers and Cantor, 1966, 1967; Pancratz and Cohen, 1968; Saayman et al., 1964), multiple-stimulus presentations (Cohen, 1968; Fantz, 1964; Saayman et al., 1964), and displays of moving lights (Cohen, 1968; Kagan and Lewis, 1965; Lewis et al., 1966).

Habituation of suppression of ongoing activity has been studied using the sucking response (Bronstein et al., 1958; Harth, 1966; Harth et al., 1968; Kaye and Levin, 1963; Keen, 1964) and limb or body activity (Engen and Lipsitt, 1965; Engen et al., 1963; Harth et al., 1968; Kagan and Lewis, 1965; Leventhal and Lipsitt, 1964; Pratt, 1934). Finally, the decrease in vocalization over trials to both auditory and visual stimuli has been studied by Kagan and Lewis (1965).

Central Factors in Habituation If the process of habituation depends on central nervous system involvement in the form of model-building of prior input, one might suspect that the rate of habituation would reflect

the relative integrity of certain brain structures. Bronstein et al. (1958) reported that habituation of sucking suppression to auditory input did not occur in about half of the infants suffering trauma at birth whereas it occurred in almost three-quarters of the normals. Slower habituation was reported in the "suspect" babies even after the signs of the trauma had disappeared and they were considered clinically normal. Absence of habituation to sound stimuli was also reported in hydrocephalic infants. Eisenberg et al. (1966) reported that whereas normal infants required from 20 to 37 trials to habituate to a modulated tone falling from 5000 to 200 Hz in 4 seconds, 2 "suspect" babies required almost twice as long and 2 high-risk babies reportedly did not habituate at all.

Age Factors in Habituation Although the role of maturation in affecting rate of habituation is an important issue theoretically, age variation is sorely underresearched. There seem to be no published studies which have explored habituation in the same infants over several months in the first two years of life, although such a study is now being carried out (Kagan, personal communication). A few cross-sectional age studies have been carried out but have usually covered only a small age range. Cohen (1968) found a somewhat faster falloff in fixation time to patterns of flashing lights over trials in 18- than in 13-week-old infants. Fantz (1964) found reduced attention to repeatedly presented pictures and increased attention to a novel picture in infants between 2 and 6 months of age but not in infants between 1 and 2 months. Lewis et al. (1966) found a fairly direct relationship between the decrement in fixation time to flashing lights and to faces as a function of age, infants generally habituated faster with increasing age over the first 18 months of life.

The literature is inconsistent with regard to rate or presence of habituation in very young infants. Fleischer (1953) and Peiper (1963) have both reported habituation of movement in the fetus to a strong auditory stimulus. Peiper (1963) also reported habituation of a respiratory response to auditory stimuli in premature babies, but Polikanina and Pobanova (1955) reported no habituation of the orienting response to sound in premature babies. They did find habituation in full-

terms Bionshstein et al (1958) discussed the findings of other Russian investigators who reported a "delay in cessation" of responding in premature but healthy infants. Analysis of age differences in habituation over the first few days of life by American investigators have generally produced negative results (Bartoshuk, 1962, Haith, 1966, Keen et al, 1965).

Sex Differences in Habituation The role of sex in determining presence and rate of habituation is somewhat perplexing. Studies investigating sex differences in newborn habituation have had negative outcomes (Haith, 1966, Keen, 1964). Meyers and Cantor (1966) reported increasing heart rate responsiveness to pictures over trials by males and decreasing responsiveness by females (5 months of age), which would suggest faster habituation by females. This finding was supported in a study by McCall and Kagan (1967) in which it was shown that discrepancy between old and new stimuli was an effective variable in the comparison of responsiveness for 4-month-old females but not for males. However, these findings to some extent are contradicted in other studies by the same investigators. Kagan and Lewis (1965) found a significant decrement in responsiveness for male, but not for female, 13-month-olds to blinking lights. Meyers and Cantor (1967) found a larger difference in heart rate responsiveness to novel stimuli in 6-month-old males than in females. Moreover, Pancratz and Cohen (1968) found habituation to pictures of geometric objects in 4-month-old males but not in females and also selective recovery of response to a new stimulus picture in males but not in females. Lewis et al (1966), studying habituation of fixation time to pictures in 3-, 6-, 9-, 13-, and 18-month-old infants, found sex of the baby to be irrelevant to rate of habituation.

State and Habituation Only Barnett and Goodwin (1965) have specifically studied habituation as a function of the baby's state. Further, such data are essential to a complete understanding of the mechanisms involved in habituation. There is the danger that many of the studies reporting age differences, the effects of birth trauma, and the effects of various parameters of stimulation have inadvertently studied the effects of state on rate of habituation.

Problems in the Interpretation of Habituation Studies

The baby's tendency to respond less and less to repeated stimulation cannot be interpreted uniformly as habituation. Appropriate control manipulations must be used to eliminate alternative interpretations of response decrement.

Studies of habituation in infants have typically been concerned with eliminating three determinants of response decrement: sensory accommodation, effector fatigue, and state of alertness or arousal. *Sensory accommodation* is generally not a problem in behavioral studies, especially when auditory or visual stimuli are used. For example, Barnett and Goodwin (1965) found no decrement in the evoked potential to sound in newborns even when 250 clicks were presented at a 1-per-second rate. However, experiments which use exceptionally long stimulus durations and brief interstimulus intervals (Bridge, 1961) may be vulnerable to the effects of sensory accommodation (Bartoshuk, 1964). Response decrement to olfactory stimuli is more difficult to interpret because the olfactory receptors adapt relatively rapidly and recover slowly (Engen and Lipsitt, 1965, Engen et al, 1964). The involvement of *effector fatigue* as an alternative to habituation can be eliminated by showing that a novel stimulus will still produce a response. Procedures used to rule out effector fatigue will be considered in greater detail later. A far more pervasive problem than sensory accommodation or effector fatigue in infant habituation studies is holding the infant's state of alertness or arousal constant throughout the experiment.

A number of studies reported earlier in the present chapter demonstrate the proposition that infantile responsiveness is affected by state. Moreover, level of arousal changes rapidly in infants and most rapidly in newborns. Therefore the possibility must be considered that, without suitable controls, findings of response decrement reflect progressive drowsiness or progressive irritation rather than habituation. A number of studies have, in fact, discussed "habituation" in a paradigm with no controls for state change (Barnett and Goodwin, 1965, Haith, 1966, Kagan and Lewis, 1965, Lewis et al, 1966, Peiper, 1963). A more subtle difficulty is that investigators attentive to the issue of alertness have

often considered "state" to be affected only by the amount of time the baby is in the experiment. An important variable controlling state, however, is likely to be the stimulus which is presented to the baby as part of the experimental regimen. For example, some studies have used strong stimuli which initially elicit startle responses (Barnet and Goodwin, 1965, Bridger, 1961, Peiper, 1925, 1963) or a concomitant of the defensive reaction such as heart rate acceleration (Bartoshuk, 1962, 1964, Bridger, 1961, Clifton et al., 1968). But a child who has been "frightened" by a strong stimulus cannot be assumed to be in the same state after its presentation as he was before. If awakened by a startle response, the infant may sink into an even deeper sleep afterward, with the consequence that he will be less responsive to additional stimulations. Wolff's (1966) observations on "freely displaceable energy," as well, suggest a continuing effect of a startling stimulus. It is also reasonable to expect that presentation of very rhythmic stimuli often used in habituation studies may produce drowsiness in babies. For example, consider the case in which infants are presented with a rhythmic stimulus for 24 trials (Cohen, 1968). As an apparent control for change in state, another group waits a period equivalent to the duration of 20 trials and then is presented with the rhythmic stimulus for 4 trials. A difference in response between the groups on the last 4 trials might reflect, not habituation, but drowsiness in the experimental group produced by the stimulus itself.

Test of Response Recovery and Dishabituation. Investigators have used a response-recovery strategy to eliminate state-change and effector-fatigue interpretations of response decrement. A second stimulus S_2 is presented after the infant's response to the first stimulus S_1 has waned. If the novel S_2 but not the familiar S_1 elicits a response, then neither variation-of-state nor effector-fatigue interpretations can be invoked to account for lack of responsiveness to S_1 . Clearly, however, one must insure, either through counterbalancing S_1 and S_2 or by other procedures, that S_2 is not *always* more effective in eliciting the response than S_1 .

Yet another method of demonstrating habituation to S_1 believed to eliminate the problem of equating responsiveness to S_1 and S_2 is

the dishabituation paradigm—first S_1 , then S_2 , and then S_1 again, are each presented a number of times. If a response decrement to a repeated S_1 is obtained which recovers after S_2 , the earlier diminution of responding is not easily attributable to effector fatigue or a consistent shift in state. However, the effect of S_2 in this paradigm may be on the state of the organism. A number of investigators have argued that S_2 does not in fact disrupt the process of habituation, rather, its presentation increases general excitability and potentiates the later response to S_1 (Sokolov, 1960, Thompson and Spencer, 1966). Only a few studies on infants have used precisely the dishabituation paradigm (Bartoshuk, 1964, Keen, 1964, Pancratz and Cohen, 1968).

Variants on the preceding two procedures have been used by a number of investigators. Pancratz and Cohen (1968) showed 4-month-old infants a geometric form (S_1) for 10 trials. The babies were then given 6 trials during which familiar stimulus trials alternated with trials on which novel stimuli were presented. A similar design was used by Meyers and Cantor (1967). In an ingenious design, Meyers and Cantor (1966) controlled familiarity on a continuum for several stimuli at the same time. Four different pictures were presented to babies in four phases. In phase 1, one stimulus (S_1) was shown 4 times; in phase 2, S_1 and a second stimulus (S_2) were each presented 4 times; in phase 3, S_1 , S_2 , and S_3 were each presented 4 times; in phase 4, S_1 , S_2 , S_3 , and S_4 were each shown 4 times. Thus in phase 4 the ratio of familiarity of the stimuli was 4 3 2 1.

Fantz (1964) used a simultaneous-presentation method to explore the effects of stimulus familiarity on fixation time. A group of 28 infants 6 to 25 weeks of age were given 10 paired-comparison stimulus presentations, 1 minute in duration, with a particular stimulus shown on every trial (S_1) and the other changed on every trial (S_2). Infants 2 to 3 months of age and 4 to 6 months of age showed a decrement in relative amount of looking at the novel stimulus over trials but no reliable effects of novelty was demonstrated for children 1 to 2 months of age or 3 to 4 months of age.

An interesting modification of the test for specificity of response decrement was carried

out by Engen and Lipsitt (1965) in what might be called a whole-part design. Two groups of newborns were first given familiarization trials in which they were presented a mixture of amyl acetate and heptanol and then tested on amyl acetate or heptanol separately. In a study using spatial shift as the dimension on which S_1 and S_2 differed, Leventhal and Lipsitt (1964) habituated newborns to a tone in one ear and then presented the tone in the other ear, and found response recovery. A still different way of testing specificity was used by Bartoshuk (1964) and by Eisenberg et al (1966). Following the earlier lead of Sharpless and Jasper (1956), these investigators first repeatedly presented a frequency-modulated tone and then reversed the order of frequency changes to test for specific habituation. Such a procedure nicely equates the amount of total energy in S_1 and S_2 but not necessarily the potency.

The problem of equal potency can easily be solved by counterbalancing assignment of the stimuli, but such a control is missing in studies of auditory habituation (Bartoshuk, 1964; Eisenberg et al, 1966), olfactory habituation (Engen and Lipsitt, 1965), and studies of habituation to stimulus location (Leventhal and Lipsitt, 1964). Reports of procedure in some studies have not been complete enough to judge whether or not adequate counterbalancing was used (Budger, 1961; Bronshtein et al, 1958). Still other studies, often cited as demonstrating habituation, have used reasonable counterbalancing precautions but have not found evidence of selective response decrements (Keen, 1964; Leventhal and Lipsitt, 1964).

The necessity for counterbalancing is often subtle. Eisenberg et al (1966) repeatedly presented to newborns a 4-second tone falling from 5000 to 200 Hz, with resulting habituation. When the modulated tone was presented in reverse, increasing from 200 to 5000 Hz, the infants showed increased response. It is possible that the infants were responding only to the early portion of the signal and that lower frequencies elicited greater responsiveness. A similar argument can be made to Bartoshuk's (1962b) study of response to patterned stimuli. In a somewhat different manner, Leventhal and Lipsitt (1964) repeatedly presented a stimulus to newborns in one ear and then tested for location-specific

habituation by presenting the stimulus to the other ear. Significant recovery of responsiveness to the stimulus in the new location was found, but asymmetry of brain or ear may have been operative (Tukewitz et al, 1966). There have been only a few studies that have used a complete counterbalanced design or randomization of stimuli (Engen et al, 1963; Fantz, 1964; Meyers and Cantor, 1966, 1967; Panciatz and Cohen, 1968).

Taken as a whole, the habituation literature confirms the notion that with experience, even newborn infants modify their responses to a wide range of signals. Few behavioral phenomena rival habituation in usefulness as a measure of the infant's sensitivity and few have as many implications for theories of psychological development. Future research on the control of habituation by variation in stimulus, age, and personal characteristics will further clarify the role of habituation in the baby's early adaptation to the environment.

THE CASE OF EARLY VISION

Considerations of Anatomy and Physiology

Although anatomical and neurophysiological differences between the visual systems of newborn and adult do not necessarily imply qualitative functional differences, gross discrepancies often provide a lead toward assessing differences in visual capacity. The eye approximately doubles in size and weight from birth to maturity (Mann, 1964), but there is great variability in growth rate from one part of the eye to another. The greatest relative postnatal gain is in the iris, ciliary body, and choroid, the growth of the lens, retina, anterior chamber, cornea, and intra-bulbar portion of the optic nerve is distinctly less than of the eyeball as a whole. The cornea is relatively large at birth and corneal refraction is high. The newborn lens is more spherical than the adult's, a fact that is probably relevant to newborn refractive processes, as is the differential development of the ciliary muscles. The retina is not fully differentiated at birth. The nuclei are closer together and more numerous in the various nuclear layers, the macula is not fully developed, and although the distance from the optic disc to the macula is the same as in the adult, a line passing through the center of the cornea and

lens will at birth strike the retina at a point between the fovea and the disc. From the eighth month of intrauterine life to the fourth month after birth, the macula undergoes constant differentiation. During this period the nuclear and bipolar layers thin, the cone nuclei increase in number, the cones themselves become highly specialized, and the fovea externa develops.

At birth the fibers of the optic nerve are myelinated, but the nerve sheath is thinner than in the adult. Myelination of the optic nerve is complete about the tenth week after birth. Although it appears fairly certain that the central nervous system (CNS) contains its entire allotment of neurons at birth, there is evidence to suggest that later cortical myelination, differentiation, and rearrangement of these neurons occurs (Conel, 1939, 1941). All in all, however, the anatomical evidence points to intact, if immature, visual structures at birth (Ellingson, 1960, Hershenson, 1965).

Physiological and neurophysiological evidence also tends to point toward relatively intact and well-developed visual structures. Contrary to the earlier findings of Zetterstrom (1951, 1952, 1955), Horsten and Winkelman (1962, 1964, Winkelman and Horsten, 1962) found cones as well as rods clearly distinguishable in the seventh month of gestation and were able to record electroretinograms (ERG) in the newborn not essentially different from those of the adult. Barnett, Lodge, and Armington (1965) also demonstrated a response to light of long wavelength in the newborn ERG. As Hershenson (1965) points out, although the maturation of the retina continues throughout childhood, there is little doubt that both the photopic and scotopic systems are differentiated and functional at birth.

It is more difficult to assess the developmental level of neurophysiological function in the CNS at birth. Bartoshuk (1964, Bartoshuk and Tennant, 1964) has shown that substantial sleep-wake differences can be found in newborn EEG records, that there is a reasonable amount of bilateral covariation, and that sustained slow rhythmicity is present. Yet evoked responses in the visual system are immature in a number of ways, they vary in form and amplitude, they show a longer latency than adult responses (Elling-

son and Lindsley, 1949, Smith, 1938a, 1938b, 1939), and their appearance is confined to the occiput, or, at best, they are found in other areas only infrequently and with variable shape and extreme sensitivity to changes in frequency (Ellingson, 1958, 1960). However, these features may only reflect quantitative immaturity—slower conduction, structural and metabolic properties of an immature brain, and a sluggish activation system (Hershenson, 1965, Hrbek and Maes, 1964a, 1964b). In sum, the neural pathways of vision are apparently functional at birth but neurophysiological indicators of functioning usually show differences in degree from the patterns of adults.

Oculomotor Facility and Reflexes of the Eye

Gross Postural Adjustments. Although the neck muscles are poorly developed at birth and the head will flop if the baby is held erect, there is evidence to indicate that the newborn, when lying on his back, can make certain immediate adjustments of the head in response to visual stimulation. Gutman (1924) reports turning away of the head from noxious stimulation in newborns. A number of researchers (Blanton, 1917, Genzmer, 1882, Moore, 1896, Peiper, 1928, Preyer, 1888, Shinn, 1893, Talbot, 1882) have observed slow, inaccurate, but nevertheless consistent, positive orientation of the head, as well as the eyes, to light stimuli of relatively low intensity. McGinnis (1930) reports slight newborn head movements in the direction of moving stripes. Lmg (1942) observed adjustive head movements to bring a moving disc into view from the first days of life onward.

Oculomotor Responses. The most convincing overall evidence that infants under 5 days of age are capable of selective oculomotor response is to be found in studies of visual preference to be dealt with later. Briefly, both casual observation and controlled experimentation have indicated that the alert newborn, when presented with two visual stimuli, will sometimes orient the head and eyes more toward one than the other (Fantz, 1956, 1963, 1965, Hershenson, 1964, Hershenson, Munsinger, and Kessen, 1965, among others). The fact that some type of differential response is possible even in this early period of life implies the presence of a certain degree of visual sensitivity. The

level of sensitivity can be assumed to depend on a number of factors contributing to selective oculomotor responding—the pupillary reflex, monocular adjustment and binocular coordination, accommodation of the lens, the area of the retina on which the image falls, and the physiological state of the receptors and receptor pathways. In addition to the general and indirect evidence in favor of early oculomotor capacity drawn from studies of preference, there exists well-controlled experimentation on specific aspects of selective oculomotor responding in the infant.

Pupillary Reflex Early researchers generally agreed that the pupillary reflex is functional and lively at birth (the evidence is summarized by Pratt et al, 1930). Sherman, Sherman, and Flory (1936) and Beasley (1933) found that the reflex, although somewhat sluggish at birth, rapidly perfects itself during the early part of the first week. Therefore it appears almost certain that there is early regulation of the light entering the eye when looking occurs under conditions of varying brightnesses. As a caution, however, it must be noted that Ling (1942) reported a positive correlation between level of illumination, duration of fixation, and number of eyeblinks in infants under four weeks of age. The finding indicated that while the pupillary reflex occurs, the newborn experiences some difficulty in adapting comfortably to increases in illumination, a difficulty that may be related to the lack of pigmentation in the iris and the incomplete development of the sphincter and dilator of the pupil at birth (Mann, 1964).

Monocular Adjustment and Binocular Coordination Almost every type of eye movement can be recorded from the newborn (Ling, 1942) but there exists virtual unanimity that control of the eyes improves over the first few months (Dayton and Jones, 1964; Dayton, Jones, Steele, and Rose, 1964; Duke-Elder, 1949; Ling, 1942; McGinnis, 1930).

The one-eye response of the newborn to simple geometrical forms has been reported by Salapatek (1967). Binocular optokinetic nystagmus has been reliably elicited just after birth in a number of experiments (Dayton, Jones, Aui, Rawson, Steele, and Rose, 1964; Fantz, Ordy, and Udelf, 1961; Gorman, Cogan, and Gellis, 1959; McGinnis, 1930).

McGinnis (1934) recorded coordinate compensatory eye movements in a baby as young as 3 days of age, but such eye movements appeared rather late in the average infant (about 2 to 3 weeks of age). Ling (1942) found evidence of coordinate compensatory eye movements at 32 hours of age but also found that until the fourth or fifth week of age, the movements were effective only for head movements of very low velocity and very limited scope.

There exist widely divergent opinions as to the time of the first appearance of binocular fixation (Beasley, 1923; Duke-Elder, 1949; Lucas, 1927; Feldman, 1920). Ling (1942) pointed out that differences in the literature are largely ascribable to differences in the definition of fixation and to the absence of a distinction between conjugate deviation and convergence coupled with the failure to record either accurately. Ling, using direct observation and photographic technique, found that, although the eyes moved coordinately in the same direction from the very first days following birth, binocular convergence first appeared as a series of small globus jerks only at a median of 4 weeks of age and did not become a smooth continuous process until about 8 weeks of age. It is somewhat unfortunate that Ling studied binocular fixation and convergence in response to a 2-inch circular disc slowly moving in and out radially through a distance ranging from 2 inches from the eyes to 36 inches from the eyes. Haynes, White, and Held (1965) have shown that the infant does not exhibit any great degree of variable accommodation until approximately 2 months of age but, rather, accommodation is fixed and appropriate only for objects about 8 inches from the eyes. In Ling's study, therefore, it is possible that early absence of convergence simply reflected a lack of the ability to maintain focus upon the disc as it moved. Wickelgren (1968), with precise photographic recording, found that divergence or ocular flare was uniformly present in the first days of life.

Research concerned with the newborn's and young infant's ability to follow moving stimuli with the eyes has tended, in more controlled situations, to find a series of jerky fixations and refixations coupled with relatively good conjugate deviations of the eyes (see McGinnis, 1930, for a summary of early work).

McGinnis found that during the first two weeks (even in the first hours after birth) movements of the visual field had a definite effect upon eye movements. However, he also found that during the first two weeks, although the majority of the eye movements tended to be in the direction of the movements of the object, the pursuit movements were often broken by large movements in the opposite direction. He also found that first sustained pursuit at three to four weeks of age consisted of many jerky refixations, but that, by six weeks of age, ocular pursuit was smooth and involved effective head movements.

Dayton and his co-workers (Dayton and Jones, 1964, Dayton et al., 1964) have provided evidence that argues for the capacity of newborn infants to pursue moving objects visually. Electrooculographic recordings were taken from each eye separately while babies were presented with dots 14 inches above the eyes. An observer judged, and marked on the electrooculographic record, when pursuit was occurring. From birth there was a remarkable coincidence of horizontal movements from each eye when the dot was being followed. However, there was a substantial change over age, refixations in the newborn varied from 1 to 1.5 per second, in the adult, measurable refixation movements rarely occurred. In the infant the frequency of these movements decreased gradually up to 3 months of age. The amplitude or the excursion of the refixations in degrees was very large in the newborn, varying from 8 to 20°, but by 3 months of age decreased to from 4 to 8°. The velocity of the eye movements was found to vary directly with the velocity of the moving dot and conjugate movements were found when the target was moved randomly at a variable speed.

Accommodation of the Lens The structure of the eye at birth would lead one to believe that the newborn eye would be farsighted (Mann, 1964). Evidence from experiments where the ciliary muscles were immobilized by atropine have almost without exception indicated the predominance of hyperopia in newborns (Cook and Glasscock, 1951, Duke-Elder, 1949, Pratt, 1954, Pratt, Nelson, and Sun, 1930, Slataper, 1950). However, as Duke-Elder (1949) points out, in the normal state the lens is not immo-

bilized and therefore can sometimes correct for extralens refractive errors by means of appropriate accommodation when these errors are not gross. Haynes, White, and Held (1965, White, 1963) tested accommodative responses under nondrugged conditions throughout the first four months after birth. The experimenters measured accommodation to a fixated red annulus with a retinoscope within four ranges of distance. Prior to one month of age the infant's accommodative response did not adjust to changes in target distance, but rather the system appeared to be locked in at one focal distance whose median value for the group was 19 centimeters. Flexibility of response began at about the middle of the second month of age, and performance comparable to that of the normal adult was attained by the fourth month.

Central and Peripheral Vision There is known to be an increase in the density and a rearrangement of macular receptors in the early months and a correlated improvement in the baby's ability to fixate centrally. Ling (1942) ignored the problem of central fixation in newborns, stating that such a question was insolvable because no test could be devised that would ascertain whether or not the image actually fell on the macula. Fantz et al. (1962) sought to answer the question by comparing the number and direction of separate fixations on a striped figure and a plain surface figure presented simultaneously to infants ranging in age from 1 to 22 weeks. Both measures indicated preference for the striped pattern in all infants. However, as Fantz noted, the stimulus object, when centrally fixated, occupied peripheral as well as macular portions of the retina.

Visual Acuity It is important in vision both to be able to get the eye to where it should be and also to be able to see clearly what is there when the eye arrives. Gorman, Cogan, and Gellis (1957), measuring optokinetic nystagmus to a field of moving stripes in infants under 5 days of age, found that 93 of 100 infants responded to stripes subtending a visual angle of only 33.5 minutes of arc.

Although Gorman and his co-workers' finding, in itself, is impressive evidence for the existence of a fair degree of visual acuity in the newborn infant, Fantz, Ordy, and Udelf (1962) have pointed out that the reflex response to a moving pattern occupying most of

the visual field may be a very different type of visual performance from the "voluntary" attention to the pattern of localized stationary objects (Riesen, 1960). Fantz et al. presented infants 1 to 22 weeks of age with two stationary stimuli at varying distances, one of which had stripes of varying widths and the other of which was a plain grey surface. It was found that the infants under 2 months of age fixated most upon the striped stimulus if the stripes were as narrow as 40 minutes of a visual angle. Between 2 and 4 months the minimum width necessary in order to bring out this preference was only 20 minutes, and for infants older than 4 months only slightly more than 10 minutes of visual angle. In a more recent study, Fantz (1965) reported even finer acuity in young infants. Dayton and his associates (Dayton, Jones, Aiu, Rawson, Steele, and Rose, 1964) add further substantiation to the impressive acuity capabilities of the newborn. They found at least 20/150 vision in newborns by eliciting optokinetic nystagmus to moving stripes of different widths.

Dimensions of Effective Visual Stimulation

Brightness. Blanton (1917) reported that many of the newborn infants she observed fixated a light. She also reported that one infant, 34 days of age, when placed in bright sunlight first shut his eyes then opened them and stared straight at the sun with his pupils constricted. According to Champneys (1881), his son, when 1 week old, looked at a candle, and bright light always gave him much pleasure throughout the first 9 months of his life. Hall (1891) observed a baby blink and turn his head away from direct sunlight on the first day of life. The infant also exhibited "surprise and fear" when he encountered a sunny window. However, on the second day following birth the infant turned his eyes and then his head toward a lamp set at 90° from midline. Watson (1925) found that newborns and infants moved their eyes toward a faint light in a dark room.

Hershenson (1964) presented 20 newborns, 2 to 4 days of age, with paired combinations of three uniform grey panels of differing brightness. He found that newborns oriented more toward the panel of intermediate than of dim or bright intensity and more toward the panel of bright than of dim intensity. Hershenson concluded that these significant

transitive preferences were indicative that brightness exists as a discriminable dimension of stimulation for the newborn. Salapatek (1968) reported interactions between brightness of figure and ground that are relevant to preference. Until preference is assessed in visual fields not containing sharp brightness transitions and in fields containing parametrically varied figure-ground brightness ratios, the exact nature of the relationship between brightness and fixation preferences will remain unclear.

Apart from the question of preference for varying brightness, a large body of experimental evidence indicates that the newborn and infant differentially respond to various brightness values in response systems other than visual orientation (Irwin and Weiss, 1934, Pratt, 1934, Redfield, 1939, Smith, 1936, Weiss, 1934). Weiss (1934) reported decreased bodily activity with increases of light intensity. Other investigators (e.g., Pratt, 1934, Smith, 1936) have found variations in activity level as a function of brightness by infants whose eyes were closed and who were presumably asleep.

Doris, Felzen, and Poresky (1968) reasoned that, because the retina at birth may be functionally more of a rod retina than a mixed rod and cone retina, it was possible that the relationship between visual acuity and brightness would not be as marked in the newborn as in the older infant or adult. They tested the visual acuity of 20 newborns under 2 levels of brightness. Doris et al. argue that the pattern of their results is consistent with the hypothesis that visual acuity in the newborn period is not as sensitive to changes in brightness as it is in the case of 2- to 4-month-olds.

Color. Color, unlike brightness, has been studied in numerous observations and experiments since the late nineteenth century. However, the failure to control differences in brightness has caused grave difficulties in interpreting the results of research on infant color perception. Color discriminations by newborns and young infants may be on the basis of brightness alone, equating colored stimuli to be of equal intensity by adult standards may be an inadequate brightness control for research with newborns (Pratt, 1954, Mann, 1965).

Preyer (1888) gave his son identical forms

of different colors. The child could not discriminate the colors until 21 months of age, when he became able to discriminate red and yellow from the series. Baldwin (1925) remarked on a 9-month-old infant who preferred blue to other colors. Holden and Bosse (1900) studied 30 infants and found that none younger than 6 months of age responded to color, thereafter, red, orange, and yellow were the preferred colors. Maisden (1903a, 1903b) held up two colored cards before his son and moved them apart to see which was preferred; later he used grasping and reaching measures of discrimination. The infant first preferred and followed the yellow card at 6 months and soon afterward followed the red card as well. McDougall (1908) found that two infants first differentially grasped colored objects at 5 months, red was preferred to green and blue. Myers (1908) found that his single subject first preferred red and yellow at the age of 6 months by grasping those colors instead of others as did Wooley's (1909) baby. In observations of several infants from 1 to 14 days of age, Canestrini (1913) found no distinct physiological reactions to different colors. After concluding that brightness and novelty influenced the babies' choices, Valentine (1914) showed that yellow and red were more readily followed and grasped.

A series of studies has used the Purkinje shift as an indication of infant color perception. Peiper (1963) in 1927 presented white and colored lights to four light- and dark-adapted premature infants. He measured their threshold with the eye-neck reflex to light flashes. Peiper found that for light-adapted subjects yellow had the greatest brightness value and, when the infant was dark-adapted, that blue had the greatest brightness value. Unfortunately, Peiper's results were not definitive, only one of his four subjects showed an unmistakable Purkinje shift of relative brightness values toward the short end of the spectrum as found in adults. Smith (1936) questioned Peiper's data and method. From a study of 20 infants in which change in activity was the measure of response, she concluded that newborn males are totally color blind and that females are partially color blind. Tincker and Tincker (in Peiper, 1963) in 1954 used Peiper's method with infants up to 10 weeks

of age and found the Purkinje shift uniformly. The degree of the shift increased with age. Pratt et al. (1930) equated colors for intensity by adult standards and measured infant's activity changes to stimuli. The results strongly supported the conclusion that responding was dependent on brightness rather than color.

Staples (1931, 1932) studied visual orientation and grasping in 262 infants from 10 weeks to 2 years of age. Colored stimuli were consistently looked at and grasped more than a grey comparison stimulus. Red was selected more than any other color paired with it. Staples concluded that color was perceived to some degree by 3 months of age. The most careful of the early studies on infant color perception was carried out by Chase (1937). She assumed that only if the infant could discriminate between colors equated for intensity would he be able to follow one color moving across a background of another color. The subjects were 24 infants from 15 to 70 days of age. Pursuit was observed in 90 to 100% of all presentations involving different colors. Control presentations (in which stimulus was the same color as the field) elicited no pursuit at all.

Sturmman (1944) measured the duration of gaze on colored cards varying in saturation, brightness, and position in 350 newborn infants. In the first two weeks of life, blue was preferred to red and green, looking time for red and blue increased during that time. Both saturation and brightness seemed to influence preferences so that the exact role of color as a stimulus was unclear.

Spears (1964, 1966) assessed discrimination of Munsell colored papers in 60 infants 4 months of age. The response measure was relative time spent looking at the various stimuli, which were presented in paired comparisons. Spears found a preference ordering of blue, red, yellow, grey with only the preference for blue over grey statistically stable. In tests of color and shape together, the only color trend was a preference for red over grey. In an attempt to control for the brightness variable, Wickelmaier (1966) presented 16 newborn infants with stimuli varying both in color and in brightness. The stimuli for the paired comparisons design were bright or dim red and grey slides. By presenting bright red and dim red slides in comparison with

bright grey and dim grey slides, Wickelmaier made it possible to find color preferences existing regardless of brightness level. No such preferences were found.

Recent studies of the electroretinogram (Barnet, Lodge, and Armington, 1965; Horsten and Winkelman, 1962, 1964) indicated that a light of strong intensity can evoke newborn ERG response to color like that of adults. Possibly stimuli bright enough to cause the newborn infant's cones to fire are too bright for the infant to look at them. If this is true, it may not be possible to use looking as a behavioral index of newborn color perception.

Despite the interest and effort that have produced studies of early color sensitivity, no positive report is free of the possibility that differences in brightness constituted the relevant stimulus dimension.

Movement. Little research has been done to determine specifically the necessary conditions for pursuit of moving objects. Jones (1926), Beasley (1933a, 1933b), Morgan and Morgan (1944), and Wolff (1949) varied the direction of movement; they studied the baby's response to vertical, horizontal, and circular stimulus movement and obtained widely different results on the basic question of the age at which the infant follows movement in each direction. Dayton and Jones (1964) found good evidence that newborn infants can pursue a moving series of dots. The presence of optokinetic nystagmus in newborns and young infants also stands as evidence for visual tracking (Doris and Cooper, 1966; Corman, Cogan, and Gelis, 1959; McGinnis, 1930; Tauber and Koffler, 1966). Beyond these studies only a beginning has been made toward determining infant preference for movement and there have not been any careful studies with techniques refined enough to determine response changes with variation in movement conditions.

One recent study of visual movement preferences in infants between 7 and 24 weeks of age was that of Silfen and Ames (1964). The stimuli were a moving and a stationary vertical belt of black and white checks. At 7 weeks there was no clear preference for movement at any speed; at 16 weeks there was a marked preference for speeds increasing up to the next-to-fastest speed used but dropping at the highest speed. At 24 weeks a pref-

erence was found for the faster speed over the entire range of speeds used. Recognizing that 7-week-old babies might discriminate movement but simply have no preference for it, Silfen and Ames (1964) ran a second experiment using several procedures to find whether infants at 7 weeks response to movement at all. Only an extension in the range of speeds produced a slight but insignificant trend toward greater response to faster movement.

Fantz and Nevis (1966) also examined preference for movement in 20 infants tested weekly in the first 6 months of life. A rotating red spot on a yellow disc was paired with a complex stationary comparison object made of wire mesh over white wood with holes. The results of the comparison showed that from 2 to 6 weeks of age the 20 subjects preferred the moving stimulus, then preference for the stationary stimulus rose to a peak at about 14 weeks and then declined until there was no preference for either object at about 23 weeks. The finding of preference for movement under 2 months is contrary to the findings in a pilot study of Fantz and Nevis as well as that in the Silfen and Ames study. Variation of color and depth in the Fantz and Nevis study makes simple interpretations hard to come by.

A group of studies have used lights flashed sequentially as stimuli. The lights have been assumed to represent movement but it should be noted at the outset that responses might be to the on-off quality of the stimulus and not to the change in position as such. Kagan and Lewis (1965) and Lewis et al (1966) studied infant attention with three patterns of blinking lights, along with other stimuli. A group of 32 infants was tested at 6 and 13 months. The patterns were a single blinking light in the center of the visual field, a blinking light moving horizontally across the field, and a blinking light that described a square helix. For all three light patterns the total looking time dramatically decreased over trials. There was no significant difference in looking time among the three light patterns for 6-month-olds, and 64 6-month-old infants run in a second experiment showed essentially the same results except that there was no decrease in looking at the helix over trials. At 13 months the original infants showed a clear preference for the single blinking light over the row and over the helix.

A study by Haith (1966) used suppression of sucking rate as a measure of responsiveness. Haith studied 41 infants from 3 to 5 days of age who were presented with lights that flashed sequentially in a rectangular pattern. Suppression of sucking was reliably greater when the light moved than when it was stationary. Cohen (1965) studied newborn preferences and modification of preferences over trials. Lights blinking in 16 positions and in 4 positions were preferred to a single blinking light. It is not clear how Cohen's finding can be made congruent with the observation of Kagan and Lewis (1965) that a single light blinking was preferred to horizontal or a square pattern in older infants.

A study of the ability of 3-month-old infants to anticipate regular patterns of blinking lights has been reported by Nelson (1968). After several exposures to a horizontal sequence of lights, the babies tended to move their eyes to the place where a light was about to appear.

Distance, depth, and size. As was noted earlier, there exists virtual agreement that one possible index of distance—appropriate convergence—is not available to the newborn (Beasley, 1923, Feldman, 1920, Ling, 1942, Lucas, 1927, McGinnis, 1930). Indeed, Wickelgren (1968) found that divergence is uniformly present in the first days of life, and, further, that the extent of this divergence varies with the nature of the stimulus (e.g., patterned or plain). In view of such findings, it is difficult to suppose that either retinal disparity or convergence could function at birth as a valid cue for distance. Nor does it seem likely that accommodatory feedback from the ciliary muscles can serve the newborn as an index of distance. Haynes, White, and Held (1965) showed that the newborn does not exhibit variable refraction of the lens as a function of variations in the distance of a test object but, rather, he exhibits fixed refraction on a plane about 8 inches from the eye. Tendencies towards appropriate variable accommodation comparable to that of an adult first begin during the second month and approach perfect performance only in the fourth month. It is possible, however, that the newborn could make use of the retinal consequences of viewing stimuli through a refractively-fixed lens. In such a system, the degree of blurring of a constant,

well-defined stimulus beyond the point of fixed refraction would be well correlated with its objective distance. Therefore, one might expect the commonly found preference for patterned stimuli in the newborn to depend on the distance of the stimuli. Fantz, Ordly and Udelf (1962) made observations relevant to such a possibility. They presented infants 1 to 22 weeks of age with a choice between a black and white vertically striped panel and a plain grey panel at each of three test distances—5, 10 and 20 in. from the infant's eyes. The "preferred distance" hypothesis was not supported by the finding that the striped pattern was preferred over the plain grey pattern at all ages and that the relative preferences for pattern was equal at all test distances.

Most reports have indicated that appropriate, stable binocular convergence for objects at different distances improves markedly during the second month (Beasley, 1923, Feldman, 1920, Ling, 1942, Lucas, 1927, McGinnis, 1930), although the accuracy of measurement in these studies is not sufficient to indicate whether or not the infantile visual system manages binocular fusion to the same degree as does the adult. Advances in the oculomotor system are, however, accompanied by rather marked changes in the infant's response to objects changing distance. White (1968b) reported that infants first exhibit partial, irregular eyeblinks to a fast approaching object at 3 weeks of age. From 3 weeks to 14 weeks the effective stimulus drop decreased and the reliability and vigor of the eyeblinks increased. Greenberg, Uzgris, and Hunt (1968) provided evidence that placing an attractive pattern over the cribs of infants beginning at 5 weeks of age could reduce the age at which the blink-response becomes regular by approximately 3 weeks in comparison with infants not provided with overhead patterning.

Obviously, however, a true distance concept involves much more than mere transitive adjustments in reflex response systems as a function of variations in the distance of a stimulus. And, with the exception of Piaget's (see especially Piaget, 1936) extensive observations of spatial development during infancy, the empirical literature on the perceptual development of distance discrimination remains sparse. Bower (1964) trained infants,

70 to 85 days old at testing, to turn their heads in the presence of a 12-inch cube at a distance of 3 feet. Following training, size of cube and cube distance were varied to determine whether retinal size was the critical variable or whether the infant could respond to absolute size. The pattern of generalization responses led Bower to conclude that the babies had size constancy and could discriminate real distance. Bower (1965b) conducted a similar study with infants 40 to 60 days of age in which the babies saw real cubes or images of the cubes projected on a screen. Discrimination of real distance, independent of retinal size, appeared to occur in both binocular and monocular conditions, however, the discrimination broke down under the "projection" condition. Bower interpreted these results as indicating that motion parallax is the necessary cue for the perception of distance in infants, while pictorial or perspective cues are virtually useless. In still a further report (Bower, 1966c) provided data indicating that binocular parallax or disparity may also be a weak, but significant, cue for distance discrimination at the two-month age level. The Bower studies are unique in suggesting the presence of real size and distance discrimination in infants during the third month of life and merit replication.

The literature on preference for three-dimensional visual stimuli underlines the expansion of the infant's world that takes place during the third month. Fantz (1961a) presented infants between one and six months of age with a solid sphere and a flat circle. Under both monocular and binocular conditions, there was a preference for the sphere when both objects were textured and directly lit. However, under binocular viewing, this relationship was not found for the youngest infants. In further studies, Fantz reported an increasing preference with age for a three-dimensional over a two-dimensional head (Fantz, 1965, Fantz & Nevis, 1965, 1967).

Experimental data bearing directly upon visually judged distance and size constancy are rare for children between 3 and 24 months of age. Naturally occurring reaching and grasping, however, have received particular attention (e.g., Bruner, 1969, Halverson, *passim*, Piaget, 1936, White, 1969) as indicative of an increasing ability on the part of the infant to execute distance-appropriate move-

ments in space. However, the increasing ability of the infant with increasing age to reach or grasp an object reveals little in itself about his ability to discriminate distance because, on the one hand, depth discrimination may precede the requisite manual skill or, on the other, because the ability may reflect only the development of a tendency to move the hand toward an object until contact.

Cruikshank (1941) observed the reaching responses of infants 10- to 50-weeks of age, toward a small rattle at 25 cm and at 75 cm from their eyes, and a rattle three times as large as the small rattle at 75 cm from the infant eyes. She found that between 10 and 14 weeks, 50% of the infants, and at 20 weeks 90% of the infants, reached for the small rattle at 25 cm. Responses to both the large and small rattle at 75 cm, however, were lower than the small rattle at 25 cm in both age groups. Moreover, with age, responses to the far distance decreased relative to the near distance. Cruikshank concluded that reaching was based on distance rather than retinal size, and that size constancy was present.

Shirley (1933) reported very similar results for a group of infants presented with a bell in and out of range, between 13 and 19 weeks less than 10% of the infants reached for the bell out of range. From 19 weeks on, there was an increase in reaching out of range which peaked at 22 weeks (70% of the babies) although reaching within range was still more common. The caution that the reaching response may not always provide a true index of the perception of distance is underscored by Shirley's comment that "babies under 6 months reached for a toy that was out of range even though they seemed to recognize that it was beyond their grasp."

Relevant to the older infant's perception of distance and depth are a series of studies indicating a tendency on the part of infants to avoid visually indicated depth when they become capable of crawling (Gibson & Walk, 1960, Walk, 1968, Walk & Dodge, 1962). Moreover, Walk and Dodge (1962, Walk, 1968) reported that a depth gradient will be avoided under monocular views although less powerfully in the early stages of crawling. Scarr and Salapatek (*in press*) provided additional evidence of the onset of cliff avoidance between 7 and 9 months of age, with

an increase in the intensity of this tendency between 7 and 13 months. Fear of depths was rare in crawling infants below 7 months, and was never observed in infants below 7 months of age who did not crawl.

Orientation and slant Watson examined the smiling of infants under six months of age to stimuli varying in spatial orientation. Twenty infants from 12 to 20 weeks of age were each presented with the experimenter's fixed, smiling, and bobbing face in normal orientation and at rotations of 90°, 180°, and 270°. The maximum magnitude of smiling and speed of first smile were considerably greater for the zero orientation of the face than for all other orientations. In a second experiment, infants between 7 and 26 weeks of age were presented a multi-colored cloth mask, mother's face, and stranger's face in three orientations. For both the mother's and the stranger's face, there was more time spent smiling at a zero degree orientation, chiefly by children 14 weeks old, than at a 90-degree or 180-degree orientation. No differences among orientations were found for the mask. Bower (1966b), employing much simpler stimuli, provided data suggesting that both shape constancy and slant perception may be present in infants during the second and third month.

Complexity, form, and faces A relatively large body of data has been accumulated on the issue of whether or not infants show selective visual attention to patterns of a particular level of complexity. In much of the research there has been the additional attempt to demonstrate a shift upwards, with increasing age, in the level of complexity preferred. For the most part, the literature has produced conflicting results; response measures used to assess visual preference vary, there is often a failure to equate for brightness and color of stimuli, and, in particular, confusion has centered around the definition of visual complexity. Some investigators have attempted to define complexity on the basis of varying *sensory* input provided by stimulation. Thus, patterns with more sides, or more angles, or more contour, or a greater number of distinct elements are generally assumed to be more complex. Other investigators have defined complexity in a more cognitive fashion. Visual complexity is seen as jointly determined by "sensory complexity" and the baby's prior

knowledge of or association to the stimulus. Thus, the preference of an infant for a geometrically simple stimulus (e.g., two eye spots) over a rather complex geometric figure at a certain age may be interpreted as a response to greater cognitive complexity because the eye spots for the first time are recognized as defining features of a face.

The distinction between sensory and cognitive complexity is relevant as well to more general questions that can be posed for early perception. First, what is the baby's congenital organization of visual form? What are the givens of form perception? The answers in the literature have not always been unambiguously stated, but several clusters of proposals emerge. The baby initially may respond to some particular element (e.g., a corner or a contour) of the visual display. He may, alternatively, be sensitive to the overall complexity, however defined, of the presented stimulus. Or, and not necessarily in contradiction with the foregoing propositions, the infant may be sensitive to aspects of the environment that are of significance for him, the prime instance, of course, is the human face. Still another congenital strategy for handling visual stimulation may be a responsiveness to discrepancy, to the violation of an expectation.

Tied to the question of initial sensitivity is, of course, the question of the mechanisms for change. How does the child come to perceive the visual world in terms like those of the adult? Although the question is of central theoretical significance and has been treated at some length by theorists of perception (see Gibson, 1969, for a general review), there is little subtlety in the empirical studies addressed to the question of perceptual change. The bulk of the work has turned on the important but insufficient issue of whether or not complex visual functioning is available to the child without specific experience with environmental contingencies.

Not surprisingly, the variety of method that has marked other research with infants holds for the study of complexity and form. Stimuli have been presented singly or in pairs; measures have ranged from human judgment to precise photographic recording, the stimuli themselves are wildly assorted—dots, geometric forms, faces, and intricate constructions, among others. And, throughout

the literature, not only of complexity but of perceptual studies with infants more generally, there arises the question of the distinction between preference and discrimination. A baby may have a fully adequate representation of a stimulus but still not provide evidence of his ability to detect it. As usual in the assessment of infantile capacity, there are likely to be many false negative results.

The studies that are reported in the next pages have all been designed to produce observations that will illuminate our understanding of the infant's early responses to visual complexity. Of course, in many of them, the definition of complexity can be stated in terms other than the terms used in reporting the research. To take one oft-noted example, a number of variations in complexity can also be seen as variations in number or length of contours.

Sturmman (1944) measured differential fixation on a patterned surface as compared to a homogeneous surface and found that infants as young as one day of age looked longer at the patterned surfaces. Beilyne (1958) presented infants between three and nine months of age with pairs of figures side by side, one of which was judged to be complex and the other simple. He found that the first fixation was significantly more often directed toward the more complex figures. Fantz (1958) found that infants between one week and six months old looked longer at a red checkerboard pattern when it was paired either with a solid red surface of equal area or a solid red surface with less area. However, this preference was consistently shown only after two months of age. Further evidence of preference for pattern was provided by Fantz' (1965) observation of infants between 2 days and 6 months of age who were presented with a number of different arrangements of paper squares. These studies provide evidence that, during the first year of life, there is some tendency for infants to prefer relatively complex, apparently meaningless, two-dimensional patterned visual stimuli over unpatterned stimuli. However, the studies do not permit the determination of preferred levels of complexity or of change in preference with age.

Only a few studies have varied stimulus complexity along a clearly quantifiable dimension. Typically these studies have de-

fined complexity by number of different elements in a stimulus. Spears (1966) presented five regular polygons differing in number of turns and color to four-month old infants. He found no significant visual preferences along either the shape or color dimension alone, with dimensions combined, there was a suggestion of preference predominantly on the basis of color. Hershenson (1964) found that newborns preferred a simple 4-square checkerboard pattern over a 144-square checkerboard but he found no preference for a 16-square checkerboard over a 4-square or a 144-square checkerboard. Hershenson, Munsinger, and Kessen (1965) determined that newborns looked longer at flat outline 10-turn random shapes than at 5-turn shapes. No preference was found in comparisons of 20-turn random shapes with 5- and 10-turn random shapes.

Brennan, Ames, and Moore (1965) studied the visual preferences of infants of three ages for black and white checkerboards of varying number of squares. They found that three-week old infants looked at a 2 x 2 checkerboard (Low) longer than at an 8 x 8 checkerboard (Intermediate) and at an 8 x 8 checkerboard longer than at a 24 x 24 checkerboard (High). Eight-week old children showed significantly different preferences in the order Intermediate-High-Low and 14-week old children showed an ordering preference from High to Intermediate to Low. Congruent results were found in a second study in which the stimuli were presented in pairs. The data of Brennan et al and the Hershenson (1964) findings provide some support for the proposition that infants tend to prefer patterns of a particular level of complexity, and that this preferred level of complexity increases with age. However, the proposition requires demonstration on a wider range of stimuli and for children of a wider range of age.

Additional data, although to some degree ambiguous, provide evidence that the infant organizes form from a very early age on a basis other than mere count of elements. Sturmman (1944) found that newborns prefer a horizontal line over a circle. Fantz (1964) found clear change from a preference for a red horizontal striped pattern over a red bull's eye before eight weeks to a preference for the bull's eye over the striped pattern.

from about eight weeks to six months. In Fantz' (1965) study of varying arrangements of squares, patterns were significantly preferred over the plain grey square at all age levels but, somewhat surprisingly, the response to grey increased significantly with age. Occasional changes in preference for the five patterns across age are also difficult to interpret. A regular horizontal-vertical linear arrangement of black squares was looked at longest by infants under two weeks of age but stood fourth for infants of four to six months of age. However, a 6 x 6 checkerboard ranked lowest for infants under two weeks, third highest for infants three to four months old, and second highest for four- to six-month old infants. A comprehensive set of principles has not been adduced to account for these results.

Fantz and Nevis (1965) presented forty-nine infants from approximately two weeks of age through 22 weeks of age with four patterns of black line segments—a circular bull's eye and the segments in random, radial, and horizontal arrangement. The horizontal pattern was preferred by babies under one month and showed an initial rise in fixation time (from two to six weeks), after two months, the radial and random patterns dropped in preference while the bull's eye remained high. A replication of the study with infants under five days of age showed no differentiation among the four patterns. The preferences of infants between one day and six months for four arrangements of 25 white squares on blue felt were also examined. The patterns were equally fixated by newborn infants, followed by increasing differentiation with age—a radial and a regular diagonal pattern became more preferred, a random pattern remained relatively constant in preference—value, and there was a marked, consistent decline in preference for a regular linear arrangement of squares. Longitudinal data from ten university-faculty and ten founding-home infants, presented with 18 pairs of stimuli of varied complexity once each week between 2 and 24 weeks of age, generally corroborated changing trends in preference noted earlier. Among the many observations reported for the babies was an increasing preference for a circular arrangement of circular stripes over a horizontal arrangement of linear stripes from approxi-

mately six to eight weeks on. The same was true for a checkerboard over a regular lattice arrangement of squares, for a polka dot pattern over a many-turn random shape pattern, and for a red checkerboard over a red square.

In a study of infants between 10 and 13 weeks of age, Graefe (1963) presented two stimuli in a central adjacent position and then moved them apart slowly, noting which stimulus the infant followed visually. Graefe's patterns and the infant's response to them are shown in Figure 3. Although some of the differences obtained are striking they do not lead to clear-cut interpretation.

The emotional reaction and visual orientation of 8-, 9-, and 10-week old infants toward punctate or continuous circular outlines, either regular or grossly distorted, were reported by Lang (1966). At eight weeks of age infants showed no differential perceptual behavior towards the stimuli but, by 10 weeks of age, the babies showed a more relaxed approach to the regular circular forms than to the distorted forms, whether punctate or continuous.

A number of studies have been concerned with the baby's response to visual figures with social significance, especially human faces. Generally, the data indicate that, at birth, patterns with social significance are no more preferred than meaningless geometric figures with approximately the same amount of patterning. However, beyond the first weeks of life, faces, human figures, and other social objects appear to become increasingly capable of attracting attention regardless of the amount of patterning. Stechler (1964) found that newborns preferred a schematic face to a diagonal of three dots and the diagonal to a blank stimulus, however, contour, as well as "faceness," varied in the stimuli. Fantz (1963) found that infants from 10 hours to 5 days of age looked longer at a schematic black and white face than at newsprint, more at newsprint than at a black and white bull's eye, and more at the bull's eye than at a red, white, or yellow plain surface. With another group of infants under one week of age, (Fantz, 1966) patterned ovals were preferred to plain ones or ones with fewer features but no consistent differential fixation in favor of faces with features in the correct arrangement as opposed to scrambled faces.

Fig 3 Pairs of patterns used by Graefe (1963) to study differential following of infants' eyes. Directions of difference in preference and associated levels of significance are shown above each pair of patterns.

was shown. Heishenson (1964) has also reported indifference to faces in newborns.

Fantz and Nevis (1967) found that an oval with "eye spots" correctly located was slightly preferred by institution infants from the first month to the sixth, that a head model with painted features was not reliably preferred over a photograph of the model until 20 weeks of age, and that a correct arrangement of schematic facial features was not reliably preferred over the scrambled features until late in the first six months. Fantz (1961b) had shown earlier that infants from four to six months looked mostly at a diagram of a red and black "real" face, somewhat less often at the same face with its black features scrambled, and largely ignored an oval if its surface merely contained a solid area of black equal to the sum of the features on either of the former figures.

Thomas (1964) recorded length of fixation time of infants ranging in age from 2 through 25 weeks to four stimuli presented in permuted pairs. He found that for the 25 infants from 2 to 14 weeks of age, the order of increasing preference for the stimuli was two broad horizontal stripes, a stylized human face, a stylized clothed human female figure, and a checkerboard pattern. In contrast, the 24 infants between 15 and 26 weeks of age looked increasingly longer at stripes, checkerboard, figure and face. Lewis, Meyers, Kagan, and Grossberg (1963) presented 16 male and 16 female infants 24 weeks of age with six different pictures—a male face, a female face, a bull's eye, a checkerboard, a nursing bottle, and a panda bear. A slight difference was found among the six stimuli with male and female faces attracting somewhat longer fixations than other patterns.

The persisting problem of whether the baby's preference was determined by "faceness" or "complexity" was tackled by Haaf and Bell (1967) by presenting four-month old infants with four stimuli differing in an uncorrelated fashion along the dimensions of degree of "faceness" and amount of pattern detail or complexity. The order of preference, indicated by duration of fixation, perfectly paralleled the ordering of stimuli along the dimension of faceness but not along the dimension of complexity.

A final recent research concern in the realm of infant perception, preference, and dis-

crimination has centered about the age-old question of part- and whole-form perception. In an attempt to discover the features to which newborn infants were attending, Salapatek and Kessen (1965) photographically recorded in some detail their visual scanning of a blank surface and of a plane triangle. The size of the infant's scan pattern was far smaller when a large triangle was in the field than when the field was blank. Moreover, for the large majority of newborns, the eyes were directed toward an angle. Thus, the newborn can select and maintain a focused scan on a relatively circumscribed feature of a visual pattern. Salapatek (1968) presented newborns with black and white, solid and outline, plane geometric circles and triangles of each of three magnitudes, and with a plain homogeneous control field. In general, the results replicated the earlier study: (1) on the plain surface, infants scanned extensively, more broadly in the horizontal than in the vertical dimension, (2) with the introduction of any geometric figure, there was a significant decrease in the scope of the scan, and (3) many newborns examined only a very limited portion of the figure, even when it was of the smallest magnitude. Unlike the earlier study, however, angles were not necessarily the part of the triangle regularly selected for direct inspection. The infants' scan was more compressed on smaller than on larger figures and there was some tendency for infants to avoid directly inspecting figures whose centers were bright. The studies suggest a rather limited selection of features for inspection by the human newborn. Data recently collected by Bower, however, strongly suggest that by the second or third month of life, the infant may process visually rather extensive general properties of an object (Bower, 1965a, 1965b, 1966c).

Clearly, the child at three months still has a long way to go toward the organization of his visual surround. The foregoing pages have dealt with only the beginnings of the sophistication of vision and the critically important integration of vision with other activities of the infant.

CONCLUSION

This chapter does not provide a map of a well-charted terrain, rather it contains hints

about ways through the forest Much more is known about human infancy in 1969 than when Darwin wrote about his son in 1876 or when Piaget wrote about his daughter in 1927, but the distance gone is a small part of the distance yet to go The bibliography

which follows these pages is a strange mixture of false starts, wise guesses, tedious documentation, clever design, and a few insights that hold hope Comforting and frustrating, the complexity of the infant continues to mock the simplicity of his students

6. *The Onset and Early Development of Behavior*

LEONARD CARMICHAEL

HUMAN FETAL BEHAVIOR BEST UNDERSTOOD BY COMPARING WITH EARLY BEHAVIOR OF OTHER ANIMALS

This chapter is primarily concerned with the development of behavior in the human infant before birth. At the outset, however, we must emphasize that the first responses of the human fetus and the gradual emergence of more and more complex patterns of behavior during prenatal and early postnatal life can best be understood when considered in a general biological setting. The comparison of the behavior of the human fetus before birth with other mammalian fetuses is much more illuminating in understanding what the young human organism can do than is a comparison of the behavior of the adult human being with the behavior of any other adult mammal. The mental life of the fully grown, effective, modern human being in so many ways depends on language and on almost incredibly complex cultural learning that a comparison with organisms that do not use real language or display behavior related to cognition, which is in large measure dependent on cultural learning, has limited significance. The difference as adults between man and even the highest of the other apes in the use of language and all that language involves for mental life has been emphasized by Chomsky (1968). The prelinguistic child, on the other hand, is in many respects a mammal among mammals for comparative purposes. Thus much that is vitally important about the behavior of the human fetus or the young child can be learned indirectly from comparative animal studies. This is because controlled experiments may be conducted on immature mam-

mals, other than man, that would be impossible with human subjects. Nature, too, has organized what may be called a series of important experiments in this field. Different species of animals are born at very varying levels of functional maturity. Some, like the opossum and other marsupials, are at birth in certain respects comparable to early human fetuses. Others, like the ungulates (e.g., the typical African antelopes), are so far advanced at birth that their locomotor and perceptual abilities are almost as effective as they are in adults of the same species. In animals born in a "precocious" state it seems clear that the growth processes of fetal maturation rather than individual learning have produced the behavioral capacities that are uniformly seen in prenatal life and in the first hours after birth. In comparison, it becomes clear that the human baby at birth is not as immature as the marsupial nor nearly as far advanced as the ungulate. A proper understanding of the complementary roles of maturation and learning in the development of human prenatal and postnatal behavioral capacity can thus be illuminated by comparing early prenatal and neonatal human behavior changes with the fetal and early postnatal behavior of a variety of other mammals.

The word *altricial* is often used to describe species (sometimes including man) in which the neonate is largely helpless and requires much care and nursing by adults. This term has long been applied to birds such as doves and pigeons which are hatched naked or nearly naked and thus need the warmth of the nest and care by parents if they are to develop normally. This term is now used not

only in ornithology but to describe mammals born in a relatively immature state. The word *precocial* is used as applying to certain species of birds (called *Praecoces*). This term applies to hens, ducks, and other species that are so far advanced at hatching that they can follow the mothers and feed themselves. Such birds, in general, belong to nidifugous (i.e., species of birds that leave the nest soon after hatching) and are mainly ground nest builders. The term precocial is also now applied to mammals that are born with well developed sense organs and with a capacity for effective locomotion at birth.

In this chapter, after the concepts "behavior" and "development" as applied to early life have been discussed, a review is therefore given of some of the known facts of the development of behavior in nonhuman animals and especially fetal mammals. The history of man's interest in human prenatal life is briefly presented in connection with some of the topics that are treated. On the basis of these considerations, modern scientific studies of specifically human fetal behavior are described and evaluated.

THE DEFINITION OF THE WORD "BEHAVIOR" AS USED IN THE STUDY OF FETAL LIFE

When the word behavior is used in this chapter, it will be considered as applying in a very general way to what the organism is capable of doing at any developmental level. In the past some students have attempted to distinguish between behavior, at least as seen in adult life, as studied by psychologists, sociologists, and other "behavioral scientists" and behavior as studied by physiologists. This distinction may have validity in some studies of adult human beings but it does not apply in the description of prenatal or early neonatal behavior. It is convenient in the mature man or woman to differentiate between "psychological behavior," which is related to such matters as problem-solving, memory, "thought" and the use of language, as distinct from "physiological behavior," which involves human reflexes such as breathing and other patterns of response important, for example, in the ingestion of food and in reproduction. But this distinction cannot expediently be made in

describing behavior observable before birth or in early postnatal life (See Lehrman, Hinde, and Shaw, 1965).

Ethologists and other modern zoologically oriented students of animal behavior are probably justified in classifying some of the behavioral systems that they record and study in animals in terms of the ends or objectives that such behavior appears to the human observer to secure for the animal under study. One example is the list used in the study of dog behavior as given by Scott and Fuller (1965). These authors use the terms investigative behavior, shelter building, grooming, feeding, attention-getting, fighting, predation, escape, dominance seeking, sexual behavior, eliminative behavior, and comfort seeking in describing what dogs do. But terms such as these are seldom appropriate in a consideration of fetal responses. It is true that one who wishes a description of fetal behavior in terms of what it does *for the organism* at the time that the behavior act appears can assert that such responses often seem to prepare the organism for some specific later function. For example, many mammalian fetuses show rhythmic limb activities that can be called trotting movements long before birth. These patterned responses, like a great many others that regularly take place before birth, may be considered "trial runs" of behavior sequences serving no specific fetal function. Such behavior is nevertheless very important at developmental periods later in life. Fetal responses, like the "Ahlfeld movements"—the premature breathing movements of the fetal chest—may not only help prepare this important respiratory mechanism for later air breathing but also may have some purely prenatal function in facilitating fetal circulation.

The fact that behavior sequences can be commonly called out by experimental means at a time in development *prior* to that at which they ordinarily play an essential role in the life process of the organism has been proposed by the present author as a basic law of development. It has been named by the present author *the law of anticipatory function*. This law points to the fact that the maturation of behavior follows a predetermined course, which largely depends on the genetically determined structural growth that takes place in an environment that is

"normal" or "characteristic" of the environments in which the species of organisms under study have evolved and in which they can maintain themselves. To put this another way, this law asserts that it is biologically essential to have the structures that make later adaptive responses ready at a period somewhat prior to the time when such reactions must work if the animal is to survive and lead a life that is characteristic of its species. This timing of developmental functional capacity as seen in all typical units of behavior is almost certainly determined by the genetic code.

In general, what has been said in the preceding paragraphs makes it clear that behavior as it is observed in fetal life and indeed to some extent in early neonatal life is best described in objective and measurable or at least potentially measurable terms. This measurement involves change in space of a total organism or in any part system of such an organism such as can be seen in neck or head bending or in limb movement.

THE MEANING OF THE WORD "DEVELOPMENT"

The second major word that is used in the title of this chapter is "development." The key to understanding the study of the growth of any organic structure or function in the *individual*, that is, in *ontogeny*, or in the *race*, that is, in *phylogeny*, is *emergence*.

Names such as the "doctrine of levels" and "creative synthesis" have been applied to the concept of emergence in organic development. The point that this term emphasizes is that as structures or processes grow or evolve, new totalities come into being not only by a simple adding together of what has been present and observable before but also by a creation of truly novel items which have genuinely new properties.

The failure to recognize the fact that novel characteristics must be described as aspects of new totalities and not as somehow hidden in the elements that make up these totalities has been called the error of potentiality (Lange, 1925). This classical mistake has been described by some logicians as the source of many of the world's worst metaphysical as well as scientific fallacies. To say this in other words, the error of potentiality

is a mistake leading to the assumption that because certain antecedent events or properties can be demonstrated to be always necessary in order to have a known subsequent event or property, therefore the full physical or other characteristics of the later-formed totality are somehow present in the simpler elements that are always present when the new totalities are formed. Oxygen and hydrogen are necessary if we are to have water, but "wetness" is not a characteristic of either of these gases before combination. C. Lloyd Morgan (1923), a distinguished classical student of animal behavior, has well pointed out that in the study of what animals do, it is best to assume that any organic capacity is not present until it can be observed (see also Lovejoy 1926, 1936, 1957, Ralston, 1933).

Thus, in this chapter, in considering the novel emergence of specific acts of behavior as any individual grows, we do not intend to suggest that such a response at any stage is to be "explained" completely because of any previous reactions of that organism as a fetus or as a neonate. The point emphasized is, thus, that behavior typical of each species at every developmental stage is, as such, a fact of science. As King (1968) has said, "not only is there a constant interaction between endogenous developmental processes and the environment during ontogeny, but natural selection is also constantly molding ever more intricate interactions." But this does not mean that it is not important to know the history of each organism for anyone who wishes to understand the emergence of any act of adaptive or maladaptive behavior at any developmental period. The questions that must occupy us are concerned with the objective descriptive stages of behavior and with temporal stages of growth. To understand these growth processes, we must ask when does a particular behavior act first appear in ontogeny and how does it change as the animal matures?

WHEN DOES BEHAVIOR BEGIN?

Many of the early writers on child psychology, such as G. Compayre (1896), used to teach that the study of child psychology begins at birth. Throughout the history of biological sciences, however, the incompleteness

of an assertion such as this has been obvious to many writers. Today it is safe to say that we must study the prenatal period if we are to determine what Gesell (1928, 1929a) has well called the "ontogenetic zero" of behavior or mind.

Ordinarily, in considering any mammal, ontogenetic development is taken as beginning at the time of individual fertilization. Under normal conditions in order that fertilization take place, there must be antecedent life in both the ovum and the sperm before true fertilization. Even though living material may some time in the future be synthesized from nonliving material, it is a safe working rule to accept the dictum "All life comes from previous life." Each new mammalian individual, then, must be considered as beginning in processes initiated at fertilization but also as a continuation of life processes existing in the male and female germ cells before fertilization.

It is thus impossible to say that fertilization is, in all senses, the beginning of the new individual. Some specific characteristics of all reproductive cells can be traced back unchanged through countless generations. Logically, it is difficult to distinguish between the dynamic processes that are essential in structural development and the later observed processes of the organism, which we call behavior. This distinction, indeed, can be made only by the use of agreed-upon definitions. In this chapter, the beginning of true behavior, and hence the starting point of ontogenetic behavioral psychology, is to be placed at the point where neurally induced muscular activity begins. Such neuromuscular response can be shown to take place only after prior activities of a special sort have developed in the central nervous system (i.e., that lead to so-called "spontaneous behavior") or in external environments that initiate sense organ activity and determine coded inputs in sensory nerves that lead to central nervous activity and to the activation of motor neurons and then to response of muscles or glands. Much that is important in understanding the ontogenetic development of behavior patterns in man can be gained from a modern comparative study of identifiable behavior patterns as seen in phylogeny (Carmichael, 1936, 1954).

It is easy to deal with the emergent or

novel creation of behavior in the abstract, but, when one turns to specific experimental studies of this emergence, the difficulty of the problem becomes clearer. This author has studied in some detail, as will be noted later, the very first responses of many organisms. For example, let us take the guinea pig fetus. Logically, it is clear that there must be a time in growth when stimulation of this organism's receptors will not be effective. Then, at an immediately subsequent time, say 1 second later, when such stimulation is given, behavior results. At time A this response is not possible, but after added growth—that is, at subsequent time B—it is possible. The possibility of this first response is considered as dependent upon elaborate changes which include growth and which are taking place in the organism under consideration. Let us trace these changes back in the history of the individual. Cell division, cell differentiation, cell migration, organ formation, and a whole series of other dynamic changes are essential before behavior begins.

As a result of all this growth, a structure capable of making this first behavioral reaction *emerges*. Without these countless antecedent cellular and subcellular processes, the first external response of an appendage or of the trunk of the living organism could not occur. These processes, moreover, must not be thought of as a simple unfolding of preformed organs. This old "preformationism view," which is a typical biological expression of the error of potentiality discussed previously, is no longer held. Rather, at each stage the living organism is now considered to be maintaining itself in a dynamic relationship with the energies and the foodstuffs of its environment. This is not to say that the organism is being formed wholly by its environment, as the other old and now long-discarded view, that of "epigenesis," held. Indeed, today it is clear that inheritance and environment always cooperate in development. The old quarrel between preformationism and epigenesis is now seen to have been sometimes a battle of words engaged in before relevant facts were known.

The discovery of the mammalian sperm in 1677 by Van Leeuwenhoek and of the mammalian and human ovum by Karl Ernst von

Baer (1827) are discussed in a full historical setting by G. W. Corneil (1958). One who is interested in a modern summary of the growth of the anatomical processes on which behavior depends may consult A. E. Needham (1964). Details of this growth are now recognized as dependent on the genetic code or DNA (deoxyribonucleic acid) and on RNA (ribonucleic acid), which can be described as picking up and carrying the message of the code into the cytoplasm, where it supervises the formation of proteins.

A number of technical terms that are now commonly used by those who consider this development of the individual in relation to its genes and the environment in which it exists may be introduced here. The term *gamete* refers to a male or female reproductive cell with half the typical number of chromosomes of the species. When a gamete combines with another gamete, a diploid cell or *zygote* is produced. In other words, the zygote is a fertilized ovum, formed by the union of reduced male and female reproductive cells. The organism considered as a complete assemblage of its genes is called a *genotype*. The individual organism that develops from the genotype is called a *phenotype*. It is important to remember that organisms with the same phenotype may not have the same genetical constitution. An organism showing certain dominant factors may have inherited different recessive factors, as is explained in the modern science of genetics.

The chromosomes with which each fertilized ovum starts life contain information for a set of enzymes that are in the genes of each chromosome. This is the "blueprint" or "coded punch card" that is the DNA, which as a totality constitutes the genetic code. It is important to remember that in evolutionary terms, each organism's genetic code has evolved and survived because organisms with that code have been able to react in an adaptive way to their environments. Thus, as will be emphasized later in this chapter, the "information" in the code is, in one sense, environmental information.

This chapter is not the place to review the complex quantitative science of modern genetics. The reader who is interested may consult the following books and references given

in them: Burdette (1963) and Fuller and Thompson (1960).

It is, nevertheless, appropriate to note here that during the last few decades much information has been secured concerning what is now often called "genetic disease." Under this heading are included many characteristics of the behavior and in the broadest sense the psychology of the developing human infant. Evidence shows that there is a basis—a genetic basis—for many bodily malformations seen at birth, some forms of mental retardation, and certain neural and sensory defects. In fact, there is some evidence that there are now known more than 300 so-called "hereditary diseases" (Lock, 1962). All this evidence points to the importance of an understanding of genetics in a consideration of the early development of behavior. In this connection, note that there is increased assurance that embryos with chromosomal anomalies are frequently aborted. It has also been shown that in the human being the percentage of chromosomal abnormalities in early spontaneous abortions is higher than in abortions occurring after the twelfth week (Jacobson and Bartel, 1967). There is some evidence that 2% of infants have congenital defects recognizable at birth (Lock, 1962).

The importance of chromosomal defects in relation to human mental life is nowhere better illustrated than in recent studies of mongolism. This subject and the research papers on which present knowledge is based are well reviewed in a paper by C. B. Jacobson (1967). The basic defect in Down's syndrome (mongolism) was uncertain until the development of modern cytogenetic techniques about a decade ago. An extra chromosome (trisomy) has been consistently found in over 95% of individuals who show Down's syndrome. This chromosomal characteristic is present in all tissues studied in individuals showing the syndrome.

Information of the sort just given shows how the student of the development of behavior must keep in view the findings of modern genetics as well as all the factors that determine embryological growth.

The processes basic to the reproduction of living animals are brought about in a number of different ways. In some animals the egg, after fertilization, continues to develop in protective coverings still

within the maternal body. In other animals the egg leaves the body and continues development outside. In many animals the growth of all the fundamental organ systems is complete before hatching or birth. This condition may be considered as characteristic of many vertebrates, some worms, and certain arthropods. In the coelenterates, insects, and vertebrate amphibians, varying stages of growth after the new organism emerges from the egg are the rule. Common usage seems to have established the fact that the first stage of the development of any organism is to be described as *germinal*, the next stage as *embryonic*, and the latest stage preliminary to birth as *fetal*. The word *larval* is used to characterize independent, living, but organically immature organisms.

In describing larval development, two classes of such growth, direct and indirect, have been set up. In the first, development is linear—that is, each developmental stage produces an organism which is in most respects more like the adult than was the organism in its preceding stage. In the case of indirect larval development, however, organs often of a high order of complexity are produced which are later destroyed before maturity is reached. The term *metamorphosis* is applied to development of this latter sort. The terms *larval* and *pupal* are applied to describe stages in indirect development. Too little is known concerning the effect of environmental modification during the larval stage upon adult animals. This is a field in which more experimental investigation is almost certain to be done. For example, what influence will certain experimentally induced forms of activity in the wormlike larva have upon the fully developed *imago*, such as an adult butterfly? It is interesting in this connection to notice that among writers even on so-called inherited human instinct many examples are taken from types which pass through larval stages (cf. Bergson, 1911, McDougall, 1923, Thorpe, 1963).

The degree of maturity reached before the new organism begins an independent existence varies markedly from type to type. In so-called *oviparous* species, such as most fish and certain amphibians, eggs are laid as single cells and are subsequently fertilized after they have left the mother's

body. In *viviparous* animals, such as certain fish and most mammals, on the other hand, all the early developmental stages are normally passed within the mother's body. Between these two extremes are the so-called *ovoviviparous* organisms, in which fertilization takes place before the egg is laid. Birds are good examples of this type. It is interesting to note that the so-called evolutionary level does not give a clear indication of the sort of reproduction which may be expected of an animal. The common dogfish bears its young inside the body until they are developed so that they may have an independent existence. On the other hand, the monotremes among the primitive mammals lay eggs. There are, moreover, certain forms in which favorable or unfavorable environmental conditions seem to determine the fact of the hatching of eggs inside or outside the mother's body (Hertwig, 1912).

Among the mammals, as already noted, it is also interesting to observe that there is a great diversity in the degree of development that has been reached at the time of normal birth. Thus the young of the opossum are born in many respects as relatively early embryos, as contrasted with the newborn guinea pig, in which almost full-grown characteristics are observed (Hartman, 1920, Avery, 1928). This fact should be kept in mind at all times as these pages are read. To put this in another way, it may be said that the behavioral age or even the "mental age" of different species of mammals is very different at the time of birth. Montague (1964) emphasizes the fact that in some species the newborn organisms are almost as dependent on the mother as they were before they were born. In fact, no one can fully understand fetal and neonatal behavior without studying in detail the maternal behavior of each species of mammal that is being considered (Rheingold, 1963).

Cornet (1944), in his admirable book, *Ourselves Unborn: An Embryologist's Essay on Man*, presents a clear description of the anatomical development of man, taking into account its aberrations. He says "we begin our lives in continuance of a long past and in progression toward an unseen goal, that life is precarious from the first day to the last."

Flanagan (1962, in a popular and very well illustrated book, gives a summary of human embryology and an excellent account for the nontechnical reader of some aspects of human development during the first nine months of life

THE DEVELOPMENT OF BEHAVIOR IN THE LOWER VERTEBRATES

There are stages in the morphological development of the fish, amphibian, reptile, bird, infrahuman mammal, and man which are so similar that they make the study of one form important for a complete understanding of the development of other forms. This fact has long been recognized in anatomical embryology. By analogy, the

same may be held to be true of behavior. Care must be taken, however, not to pretend to see homologies of behavior until by direct observation such homologies can be shown to exist. Figure 1 gives a somewhat too idealized picture of some of these relationships. For example, in certain forms nourishment during the entire fetal period is provided by the yolk of the egg, from which the organism develops. This means that behavior in connection with alimentation is less important in such types than in others in which at an early developmental stage the ingestion of food is necessary. In spite of this difficulty, the study of fish and amphibians has provided much information of importance to one who would understand the gradual development of behavior. Swen-

Fig 1 A series of drawings constructed to emphasize similarities in structure in various embryos at three comparable and progressive stages of development (marked I, II, III) (From Romanes, 1896) This old diagram is presented here as a schematic device only. Research since it was drawn has made some alteration in the relationships demonstrated here. See for comparison diagrams in Ferris (1922)

son (1928a) has courageously attempted to set up seven fundamental acts of behavior as basic to the responses of lower vertebrates, mammals, and even man. These forms of behavior are progression, respiration, ingestion, expression, excretion, phonation, and reproduction. The fact that some of these processes can be studied in the amphibian larva as well as in the human infant makes the complete understanding of the simpler organism especially important. Coghill (1929c) and others (e.g., Windle and Griffin, 1931) have developed this point of view in various papers. A good history of the development of the study of vertebrate embryos is given by the scientist who did so much for the study of behavior that he may be considered the founder of the experimental study of early behavior. This man is William Preyer, for some years professor of physiology at Jena. His book, *Specielle Physiologie des Embryo Untersuchungen über die Lebenserscheinungen vor der Geburt*, published in 1885, may be taken as a subsequent investigation in this field. Part of this fundamental work has been translated by Coghill and Legner (1937).

In this work Preyer summarizes and reviews a good many observations made on the early movements of fish embryos. Some of these studies were based on the observations of fish embryos growing after definitely dated periods of fertilization. Slow rotary movements characterize the early behavior of many fish embryos. Fillipi is quoted by Preyer as finding in *Alosa finta* such movements soon after fertilization. In a species of trout Preyer found movement of trunk at a definite number of days subsequent to fertilization. In general, on the day following the first trunk movement the first neck-head movement is noted. Then, in a few days, energetic movements of the whole tiny fish body may be observed. After the liberation of such organisms from their egg coverings, it is found that pressure stimulation on the body surface is followed by responses involving apparently the entire musculature of the trunk. Preyer points out that these movements involve fully developed reflexes. He makes this conclusion because the movements described consist in the total organism's drawing together of the head and tail. This same response occurs no matter what the

locus may be of the point of pressure stimulation. As growth goes on, however, the strength of movement increases, and the movements become more and more regular and specific in relation to the exact locus of the area stimulated. Preyer gives quantitative tables of the increase in rapidity of the movements of the heart and the gills as development progresses. Myrberg (1965) has presented a full descriptive analysis of the behavior of the African cichlid fish. Parental behavior, egg incubation, and the establishment of the free-swimming phase are discussed.

White (1915) describes the development of behavior in brook trout embryos. His observations cover the period from hatching until the yolk sac is absorbed. He notes that "the hatching is initiated by movements starting at the head and later extending through the whole length of the body." After hatching, the swimming reaction is gradually made more nearly perfect. Touch and mechanical jars are effective stimuli immediately after hatching, and, interestingly enough, at this time the head is found to be the region least sensitive to pressure stimuli. Rheotaxis, or response to water flow in currents, negative phototaxis, or the avoidance of light, and photokinetic responses, or responses initiated but not necessarily directed by light, are also present at this time. Excess carbon dioxide in the water in which fish are studied is activating up to a point, and then depressing on bodily functions. The dependence of the fish upon the chemical make-up of its external water environment presents many analogies with the dependence of the higher animal upon the chemical make-up of the liquid internal environment of its own blood stream in which its own central nervous system maintains itself. Or, to put this another way, the internal environment of the fish embryo is seen to be most closely related to its external environment. Before the nourishment-supplying yolk sac disappears at about 2 months, the reaction of the fish to stimuli seems to be away from the point of contact. After this, some embryos studied become quite suddenly exploratory and aggressive and hence move toward the point stimulated (Preyer, 1885). This striking observation may remind the reader that an intimate relationship exists between the

degree of maturation of an organism and the "drive" which the organism shows in relation to external stimulation

From the general standpoint of the development of behavior, however, the work of Tracy (1926) is especially worthy of note. This investigator has studied fish embryos, especially those of the toadfish. He has carefully observed and recorded the growth of activity in this form from its first movement to a final free-swimming condition. The first activity of the embryo in this form as in so many others is what may be termed in Parker's sense the preneuronal and "independent effector" action of the heart (Parker, 1919). The first behavioral movement of the fish is the bending of the trunk in the anterior region. At times this movement is to the right, at times to the left. It is probable that the afferent proprioceptor or muscle-sense system is not functional at first. At an early point a spontaneous flutter movement develops. This movement probably is important in freeing the organism from the remaining egg membranes. In general, toadfish larvae when hatched lie at the bottom of the containing vessel in a quiescent state. Then suddenly they move. On the basis of careful study, Tracy concludes that this "spontaneous" behavior is related to cumulative changes in the blood of the organism such that at a certain point the central nervous system is directly stimulated or the threshold of the central nervous system is so altered that previously inoperative sensory impulses break over into motor outlets. Thus he concludes that spontaneous movements are the result of metabolites and oxygen deficiency in the blood stream. Soon after the onset of such responses, the organism becomes very sensitive to external stimuli. The mucous membrane area about the mouth is the first to be sensitized. In general, the spread of sensitivity is from this point toward the tail or possibly to the region that has just become most active. The "cephalocaudal progression" of sensory and motor development which some writers propose as a law is, however, far from regular in this organism.

Tracy draws some fundamental conclusions from these studies. He holds that if external conditions could be kept constant the activities of the organism would be

determined by its own life processes or metabolism. This would mean that all behavior would be rhythmic, like that of an excised muscle in a balanced salt solution. At a later point we shall note that T. G. Brown (1915) holds that early mammalian reflexes may be of this nature. In conclusion, Tracy says "From the beginning, and more or less continuously during its whole existence, the animal is driven through its environment as a result of stimuli which arise periodically in connection with its metabolic processes." The nature of later behavior may be thought of, he further suggests, as dependent upon neural development and the interference in the intrinsic rhythms of behavior brought about by the stimulation of the special exteroceptors of the organism by external energies. The basic relevance of this observation even for adult human behavior has been considered elsewhere (Carmichael, 1947).

Development of Behavior in Amphibians

We now turn to the study of the development of behavior in amphibians. Swammerdam, in his *Bibel der Natur* (1752), written before 1685, makes observations on the behavior of frog embryos five days after fertilization and at other periods (Preyer, 1885; Swammerdam, edited, 1907). Swammerdam has also recorded observations concerning the development of behavior in snails and other invertebrates. Leeuwenhoek (1667) made observations in this same field. Among other early students of behavior in invertebrates may be mentioned Stübel (1815), Grant (1827), and Home (1827). Bischoff (1842) published a confirmation of the description of movements previously observed by Swammerdam in amphibians. He added a notation of the fact that the rate of these movements is a function of the temperature of the water in which the animals are maintaining themselves. Preyer (1885) reviews all this work as well as that of Perschke and Cramer on the amphibian embryo. Preyer himself made elaborate observations on the early movements of frog and salamander embryos. He noted that stimulating the embryo led first to a slight twitch in the anterior portion of the organism. Following this movement in time he noted that the body was bent so as to bring the head and tail nearer together. Reference to Preyer's original draw-

Fig 2 Diagram of various positions of frog embryos (*Rana temporaria*) just before emergence from the egg. Note especially the C and S reactions (From Preyer, 1885)

ings, reproduced as Figure 2, as well as to the text of his book shows that he considered these C or reverse C movements very important. It is also clear from his drawings that he observed the fundamental S or sigmoid form of reaction. The importance of this S movement in freeing the organism from the egg is pointed out. That this movement is also related to the activity of swimming is an important consideration.

Other students have worked on the relationship between temperature and embryonic movements in larval amphibians (Preyer, 1885). Many others have used this convenient laboratory type in work in experimental embryology. Much of this experimental embryology has direct bearing on the problems of this chapter (See Detweiler, 1920, 1921, 1922, 1923a, 1923b, and the bibliographies given by him).

If Preyer may be called the father of the scientific study of the development of behavior, G. E. Coghill (see references in the bibliography) must be remembered as the investigator who first charted the relationship between the detailed growth of the nervous system and the consequent alterations which occur in behavior. This investigator is notable also because of the completeness of his work on the salamander *Amblystoma*, as well as on other types. The life of Coghill with his complete bibliography by C. J. Herrick (1949) ably discusses the fundamental contributions of this original scientist to the study of behavior. Coghill's first paper in this field was written in 1902, and from that time until his death in 1941 he published a most important

series of papers on the development of behavior in relation to the growth of the structures on which behavior depends. In the course of his many papers, Coghill reported detailed studies of the neural mechanism underlying the first movement and the later sequences of movements as they develop in *Amblystoma*. The first response results from the contraction of muscles just behind the head. As the embryo advances in age, this contraction becomes, after a period of gradual transition lasting for about 36 hours, one which involves the whole animal. The result of this reaction, is that the organism assumes a position which may be described as that of a tight coil. This C or exaggerated C coil is sometimes oriented to the right and sometimes to the left. It may reverse instantly. At this point in development, all behavioral activities are initiated in the head region and progress toward the tail.

In commenting upon this sequence, Coghill (1929a) notes that at this time "Nothing really new has yet been introduced into the behavior pattern of the animal since its first movement was performed, and the coil reaction gives the animal no locomotor power. Nevertheless the coil has in it the primary locomotor factor: cephalocaudal progression of muscular contraction." The transition from this behavioral level to the S reaction is amazingly simple. One C contraction begins, for example, on the left, but before it has reached the tail another contraction to the right begins.

The components of this movement may be made clearer by consulting Fig. 3. As this reaction gains speed, its performance exerts pressure upon the water and thus drives the organism forward. Thus the S reaction becomes the basis of swimming or aquatic locomotion. This fundamental pattern of behavior may well be a peculiarly significant stage in many other types of growing organisms. This same stage is seen clearly in the swimming of the lower vertebrates. It is somewhat obscured in the four-legged mammals and still more obscured in man, but that this S reaction plays its part in the growth of behavior in these higher organisms seems to be an established fact. Five stages in the development of this basic swimming activity have been made out by Coghill (1929a).

1. The nonmotile stage, in which direct muscle stimulation by mechanical or electrical

Fig 3 Three diagrams of *Amblystoma* (a) The organism in an early swimming stage but without indication of muscle contraction (b) The beginning of a swimming movement as a first flexure by contraction of a number of anterior muscle segments (c) The swimming movement in which the first flexure has passed tailward and the second flexure is beginning in the anterior region (From Coghill, 1929a)

means leads to muscular contraction and hence to externally observable response

2 The early C flexure stage, in which light touch on the skin of any portion of the body leads to a response

3 The tight-coil stage, in which the contractions noted in stage 2 become more pronounced and the extent of the contraction greater

4 The S reaction, which is characterized by a reversal of flexure before the previous flexure has been completely executed as a coil, thus leading to the sinuous behavior of the total organism

5 The speeding-up of the S reaction so as to produce the typical swimming movement of the amphibian larva

Youngstrom (1937) in studies upon *Anura* (frogs, toads, etc) concludes that the Coghillian sequence of developing behavior applies with only slight variations to the *Anura* studied Wang and Lu (1940, 1941), too, have shown that the stages through which the frog passes are similar to those described by Coghill These investigators have also shown that severance of the spinal cord arrests the

development of swimming at about Coghill's stage 4

Coghill studied in great detail the neural structure characteristic of the salamander in each of the five stages noted above On the basis of these investigations he shows how the known structure of the nervous system may make possible the behavior which has previously been described It is important to recognize that for the most part Coghill (1929a) believed that in young organisms movement is typically away from the point of stimulation

As already noted, the salamander has, besides aquatic locomotion, other significant behavior systems Of these, walking or terrestrial locomotion and feeding require special consideration The *Amblystoma* swims before its anatomical development has progressed to the point where it has true limbs Structurally and functionally the forelimbs are in advance of the developing hindlimbs In this organism, however, at first both sets of limbs, when they appear, move only in relation to the larger trunk movements previously described as those of swimming Coghill shows why this must be

so because of the developing nervous system. Gradually, however, independence of limb action or *individuation* of limb behavior over the dominance of the trunk movements begins (1930e). First the forelimbs gain a certain autonomy, and later the hindlimbs also. "It is obvious, therefore," observes Coghill (1929a), "that the first limb movement is an integral part of the total reaction of the animal, and that it is only later that the limb acquires an individuality of its own in behavior." He then suggests that the forelimb itself may be considered to possess a pattern of development which is comparable to that of the total organism. At first, if movement occurs at all, the whole limb moves. Later, elbow flexion and wrist and digit movement in turn gain independence of the total member. It is important to recognize that during this developmental sequence the time relations of the swimming reaction may be considered as in a way superimposed upon limb activity. Thus one may, if he wishes to, think of the alternate movements of walking in a four-legged organism as a growth out of the basic trunk movements of swimming previously described. Coghill (1929a), indeed, says "Movement of the trunk in walking is nothing more nor less than the swimming movement with greatly reduced speed." Gradually the sinuous movement of the trunk is reduced as walking becomes more independent, and eventually the characteristic land locomotion of the salamander appears.

There can be little doubt that this basic and important developmental sequence is determined in each organism by its own genetic code. As we compare lower vertebrates, mammals, and man, we can see that some especially "deeply organized" aspects of this code determine such anatomical facts as bilateral symmetry, the vertebral column, the spinal cord, the attachment of appendages, and what can be called the fundamental working plan of the vertebrate. But these "deeply established" aspects of the genetic code can also be seen in behavior. The sequence of trunk bending and of patterned limb movements just reviewed can be observed at least from fish to man.

It is interesting that the C posture and the S posture are seen in certain adult fish during courtship (Myrberg, 1965).

The development of the feeding reaction

in this same organism has been similarly studied by Coghill (1929a). This response begins with a movement of the trunk, then comes a reaction which involves a sudden lunge of the whole organism, after this there is a gradual correlation between this lunge movement and the activity of the jaws and the muscles of the esophagus. In summarizing this whole development, Coghill (1929a) says "Behaviour develops from the beginning through the progressive expansion of a perfectly integrated total pattern and the individuation within it of partial patterns which acquire various degrees of discreteness." It should also be noted that as this development continues new senses become important in relation to behavior. Coghill (1930a) believes that "the individual acts on its environment before it reacts to its environment." In considering these beautifully elaborated generalizations of Coghill's, it is important to remember that in some details a different sequence in the development of behavior may well characterize the growth of a mammal and a salamander. One should not forget also that even Coghill's own neurological studies point to specific relationships between the locus of stimulation and the muscles that are caused to respond (1929a). In comparing the salamander and the guinea pig, for example, it may be noted that the limbs are quite fully formed before the first behavioral response or reflex takes place in the guinea pig, but in the salamander behavior begins before there is any real morphological forelimb at all.

In a series of papers Carmichael has presented the results of his studies of the development of behavior in *Amblystoma* and the frog under conditions such that experimental groups of animals were raised under unusual environmental circumstances (Carmichael, 1926a, 1927, 1928, 1929). A technique devised by Randolph (1900) and developed by Harrison (1904) was employed. For a consideration of the effect of the anesthetic chlorotone on the organism in question, a paper by Matthews and Detweiler (1926) should be consulted. At a period before motility had begun, numerous developing *Amblystoma* was divided into two groups. The first of these groups was used as a control. The second was used as an experimental group. The experimental group was placed in water containing the anesthetic. The control group was allowed

to develop normally in water. Later, at a developmental point previously described by Hennick and Coghill (1915), vigorous responses began in the control group. At this time the experimental group showed morphological development but otherwise remained absolutely inert because of the action of the anesthetic. However, in a short time—often only a minute or two—after the drugged embryos were placed in fresh water, they began to swim well. In fact, a number of the eighteen *Amblystoma* embryos swam so well in less than one half hour after they had shown the first sign of movement that they could with difficulty, if at all, be distinguished from the members of the control group who had been free swimmers for five days" (Carmichael, 1926a). In evaluating this work, the publication of Fromme (1941) should be consulted as this investigator reports that in an experiment similar to that of Carmichael impaired behavior of short duration was observed.

In later experiments efforts were made to control stimulation in other ways (Carmichael, 1928). These investigations led to the conclusion that the development of the neural and other mechanisms upon which behavior depends does take place in these organisms whether or not they are as individuals responding to external stimulation. This seems to have a negative implication concerning an extreme interpretation of Child's (1921) environmentalist theory of the causation of growth in the nervous system. Nothing in these experiments is to be taken, however, as invalidating the idea that the growth of the nervous system itself involves activity. Studies such as those of Burt (1932) and P. Weiss (1926, 1939) on this same organism emphasize the dynamic character of such growth processes. For a general consideration of the relationship between neural growth and the development of behavior see Hooker (1950) and Hooker and Hare (1954).

In the reptile class comparatively little work has been done, although Preyer (1885) reported some occasional observations on snakes. Tuge (1931) also did some very interesting work upon the growth of behavior in the turtle. In this work the sequence of Coghill is seen as modified by the existence of the shell which especially characterizes this form. Smith and Daniel (1947) have also made some in-

teresting observations on the early responses of the turtle.

In these relatively simple vertebrates, a principle can be seen most clearly that applies in all animals, including birds, mammals, and man. As morphological growth of an organism in its environment takes place, one can see the genetic code at work as developmental stage succeeds developmental stage. The neural mechanisms so developed can be thought of as information processing devices that have allowed organisms possessing such structures to adapt effectively to the environments in which they exist and survive. Later, each individual processes the "environmental information" acting on its own individual external sense organs in such a way that adaptive behavior results.

DEVELOPMENT OF BEHAVIOR IN THE EMBRYOS OF BIRDS

From an evolutionary point of view, the bird may be thought of as presenting an interesting comparison with the lower vertebrate and the mammal. The amphibian embryo provides unusually favorable material for morphological and behavioral developmental study. The growing salamander or frog embryo may be observed, without interference of any sort, through its translucent egg covering and in free life after leaving these coverings. Its egg yolk provides food during a long part of the early developmental period. On the other hand, the study of the development of behavior in the mammal involves relatively complex surgery and, at present at any rate, a certain disturbance of the normal environment of the growing organism. The bird embryo is harder to study than the amphibian but easier than the mammal. It may be studied in a relatively normal environment, but a special technique is necessary to render the development of the bird embryo continuously observable. Down through the years, however, the chicken's egg has been the subject of embryological study. Needham (1931) reviews the use that has been made of the hen's egg in embryology since earliest times. This writer describes the history of the artificial incubation of hens' eggs. He notes also the beginning of systematic observation of embryos taken from eggs in various periods of incubation at the time of Hippocrates

(about 460 B C) From that time on, the hen's egg has been extensively used in morphological studies of development. Among those who have contributed to this development are Aristotle, Aelian, Pliny, Plutarch, Albertus Magnus, Leonardo da Vinci, Aldrovandus, Fabricius (who made beautiful illustrations of a series of chick embryos), Highmore, Sir Thomas Blowne, Harvey, and Malpighi. Today the many admirable manuals on the embryology of the chick, such as those by Patten (1929) and F. R. Lillie (1919), present a large amount of evidence in regard to the structural development of the chick. Schenck (1965) notes that altricial birds first respond in a general way to mechanical stimuli but adaptive discrimination develops as visual and auditory clues become effective.

Preyer (1885), reviewing certain of these facts many years ago, noted that, whereas the structural development of the chick is comparatively well known, its behavioral development is not. Although advances have been made since that time, this observation is still true. A few casual observations on this development, nevertheless, were made at an early time. Harvey as long ago as 1651 noted that the chick in the sixth day of development showed a bending and stretching of the head (Preyer, 1885). About a century later Béguelin noted the heartbeat of the small embryo on the third day, and on the sixth day the oscillation of the whole body, and from that point on he records elaborate changes in movement. He records the fact that he was able to observe the development for 15 days in the same living and developing embryo (Preyer, 1885). Home, in 1822, was probably the first to note the movement of the extremities on the sixth day (Preyer, 1885). Von Baer, in 1828, published rather extensive studies on the development of behavior in the chick, in which he noted the inception of the pendular movement of the whole embryo as a result of amnion contractions (Preyer, 1885). Amnion contractions, he noted, were most marked on the eighth day and were successively less on the succeeding days. This same investigator reported general activity of the embryo on the eleventh, twelfth, and thirteenth days. The amnion contractions of the bird's egg have no complete parallel in other forms. The growing chick seems, as it were, to be tossed in a blanket as it grows. Von Baer also saw

what he considered to be the beginning of breathing movements in the 14- to 16-day embryo. Several other investigators are quoted by Preyer as having also made observations upon the development of behavior in the chick. By far the most extensive study up to his time on the development of the bird embryo, however, was made by Preyer himself. The extent of his study may be indicated by the fact that he used some 500 eggs in his experiments.

In this work Preyer gave much attention to the movements of the amnion which have been referred to above. Preyer pointed out that the rhythmic movement of the amnion when at its maximum extent, between the seventh and ninth days, leads to such an agitation of the fetus that no study of fetal activity can be made without taking these contractions into account. The amnion contractions are generally described as independent muscle reactions. They are non-neural. Preyer also describes the gradual development of behavior of the chick embryo from its earliest head movement to the behavior necessary for hatching. Since the time of Preyer there have been a number of special studies on particular aspects of the fetal and hatching behavior of the birds, such as those by Breed (1911), W. Craig (1912), Clark and Clark (1914), and Patten and Kramer (1933). For the purposes of this chapter Kuo's work is especially important. This work is presented in a series of papers (Kuo, 1932a, 1932b, 1932c, 1932d, 1932e, 1938, 1939a, and Gottlieb and Kuo, 1965). The work of Orr and Windle (1934) and of Hamburger and Balaban (1963), Hamburger and Hamilton (1951), Koecke (1958) is also very important.

To collect material for the study of the morphological development of the egg, it is necessary only to open the shells at known periods of incubation. Opening of eggs without special precaution leads to the early death of the embryo, but this is not important if the organism to be studied is placed at once in a fixative to prepare it for the histologist. A number of techniques, however, have been devised to open the shell and still allow the continuous observation of the early development of behavior in the bird. One of these methods, devised by Kuo (1932a), has yielded excellent results. Kuo's method makes possible an uninterrupted study of the developing

fetus without interfering in any essential way with the natural membranes of the egg, or, more important, with respiration of the embryo. Kuo's operation may be described as follows. The shell of the blunt end of the egg is cut off with a fine pair of scissors as far as the inner membrane. The whole inner membrane, however, is allowed to remain intact. A very small amount of melted petrolatum is immediately and rapidly applied to this membrane with a Chinese writing brush. At the temperature of the incubator the petrolatum remains liquid but, when applied by an expert, does not spread. This treatment produces a transparent membranous window through which the embryo and the extraembryonic structures and functions can be observed. This technique renders the membrane so transparent that it is almost as satisfactory as removing the membrane. In the course of observations Kuo uses three incubators, one in which the eggs are kept before they are experimented upon, another in which the operation is performed, and the third a special observation incubator fitted with appropriate glass plates through which a microscope may be used. For a criticism of Kuo's technique, see Becker (1940, 1942).

Kuo has also devised a transparent dial graded in fractions of a millimeter which may be put over the cut end of the egg, thus making the quantitative measurement of fetal movements possible. The writer has collaborated with Kuo in making a moving-picture film of the typical stages of development of the chick embryo. For the most part these pictures were taken through the membrane treated as described above. This procedure has been described (Kuo and Carmichael, 1937). In connection with this technique a consideration of the air space of the hen's egg and its changes during incubation is interesting. (See Romijn and Roos, 1938.) S. H. Salter (1966) has developed a technique to record activity in eggs while the egg remains intact. A transducer is used that resembles a loudspeaker without a diaphragm. The egg to be studied rests on a cradle on top of the apparatus so that movements in the egg produce damped oscillations proportional to their amplitude. Sound signals produced in the egg can also be recorded. The eggs used in the experiment were those of the bobwhite quail.

Using his special technique, Kuo has stud-

ied many thousands of eggs, and on the basis of this study he has made definite statements in regard to the developmental sequence of behavior in the chick embryo. This work deserves special consideration in this chapter because it is the work of a scientist who is interested in the psychological significance of behavior and because it places emphasis on the part played by the environment in the determination of the course of behavioral development. The results are also presented in such a way that they are peculiarly applicable to psychological problems.

Kuo has traced the chronology and general nature of behavior in the chick embryo (1932a), the mechanical factors in the various stages leading to hatching (1932b), the influence of prenatal behavior upon postnatal life (1932d), and many other special topics such as the relationship between acetylcholine and the onset of behavior (1939a). In the last-named study Kuo shows that the first true neuromuscular responses do not appear until after this substance may be detected. This suggests that there may be a chemical mediation of the first response of the chick. For a modern discussion of the physiology of neuromuscular transmission, see Field, Magoun, and Hall (1959). A reference to Fig. 1 will show that at one typical stage the embryo of the chick is very similar to the fetus of the reptile and, indeed, to the fetus of man. It must, however, be remembered that the arrangement of the embryo of the bird in relation to its extrafetal membranes is, as suggested above, in a number of ways peculiar. A description of this anatomical relationship may be found in Patten (1929).

Kuo's work on the chick may possibly best be summarized by indicating briefly something of the observed movement and the time at which the movement was *first* observed. It should be noticed that the writer, by using the time at which the movement was first observed, may do an injustice in certain cases to the facts as presented by Kuo, because that investigator shows that in many cases the movement does not, on the average, arise until some hours or even days after it was first observed in peculiarly favorable specimens. A summary of the commencement of the passive and active move-

ments characterizing the developmental behavior of the chick may, however, give the best generalized picture of the development of the chick that is possible in the compass of this chapter. The following activities are among those noted: heartbeat, at 36 hours, head vibration, 66 hours, body vibration, 66 hours, head lifting, 68 hours, head bending, 70 hours, trunk movement, 84 hours, amnion contraction, 86 hours, yolk sac movement, 86 hours, swinging, 86 hours, head turning, 90 hours, movement of forelimbs, 90 hours, movement of hindlimbs, 90 hours, movement of tail, 92 hours, movement of toes, 5 days, response to electricity (in an embryo removed from the shell and placed in a physiological salt solution), 6 days, eyelid movement, 6 days, response to pressure, 6 days, movement of eyeball, 7 days, swallowing, 8 days, leg folding, 9 days, fixation of body position, 9 days, bill clapping, 9 days, response to touch (in physiological salt solution), 9 days, first wriggling, 11 days, turning of body, 12 days, protrusion of neck, 16 days, respiratory movement, 16 days, response to rotation, 17 days, tearing of membrane, 17 days, peeping, 17 days, response to light, 17 days, response to sound, 18 days, response to vibration, 18 days, hatching, 19 days. Final leaving of the shell does not typically occur, however, until the twentieth or the twenty-first day (Kuo, 1932a).

Alconero (1965) has shown that grafts from 3 day chick embryos show spontaneous motility only when the grafts contain sections of the spinal cord. This supports the view that spontaneous motility observed *in vivo* is neurogenic from the beginning.

Kuo has not been content with a mere passive description of the movements indicated above in their time sequences, but in every case he has attempted to give a description of the mechanical and environmental factors which are important in determining the special movements and the special modifications of movements that he notes. Thus, for example, he points out that the beating of the heart leads to a general rhythmic vibration of the inert fetal body which starts the head into passive mechanical movement. In connection with the heart beat of the chick, it may be noted that the structural and functional change of this organ during growth has been intensively studied

by Patten and Kiamei (1933). Almost from the first appearance of the cells which are to form the organ, beating may be noted. This passive mechanical movement continues until at length it gives place on the fourth or fifth day to a true active movement. Head movement in the chick begins as an up-and-down bowing. Gradually, as a result of the change of the weight of the head and of associated structures in the egg, this up-and-down movement is changed to a sidewise movement, which is eventually inhibited by the altered relationship between the fetus and the yolk sac.

Kuo makes similar observations in regard to the movement of the appendages and to other special behavioral functions. He notes that during the period of the most forceful amnion activity, from the seventh to the ninth day, the mechanical movement of the fetus so stimulates it that there is a large increase in the active movements of the embryo. These movements are considered significant in the development of further movement. It is also observed that an active movement originating in the embryo may incite further activity of contraction in the temporarily relatively quiescent amnion. Indeed, possibly as a result of this reciprocal activation during the period of vigorous amnion contractions, the movements of the developing chick in this period are almost ceaseless. It thus comes about that every part of the musculature of the embryo has been exercised before half its incubation period is over. This fact led Kuo (1932b) to point out that any correlation which it is desired to make between the development of behavior and the development of the nervous system in the chick must take into special consideration the changing conditions of response due to morphological growth and increase in weight of the body parts themselves and especially to the changing relationships between these growing body parts and the environment in which the growth is taking place.

It is interesting to note that the specialized movements of the eye and of the eyeball occur as early as the eighth or ninth day but that the first light response of the organism does not ordinarily appear until the seventeenth to the nineteenth day under experimental conditions. Thus the eye reflexes are present in the absence of effective visual

stimuli. These early eye movements, indeed, have been found by Kuo to occur in conjunction with movement of the body in space instead of in response to visual stimuli. A similar temporal sequence in mammals and its probable mechanisms as worked out by the writer will be discussed below. Only in the later periods of development do the eyes begin to acquire a relative degree of independence from the rest of the organism. Kuo reports that in general the responses to touch, pressure, and electricity, which may be elicited from at least the tenth day onward, are similar to the normally excited responses which he has observed. In conclusion, Kuo asserts that practically every physiological effector mechanism is thus shown to be in a functional condition long before hatching. Thus the organs begin to function in many cases before they reach adult form, indeed, many function in rudimentary form. He feels that, as is true in the development of structure, too much stress cannot be laid on the fact that the development of behavior is gradual and continual. In Kuo's opinion, the early embryonic movements may be thought of as the elements out of which every later response of the adult bird is built. In this connection he points out that certain of the typical postural attitudes of the adult fowl are but returns to the tonus condition of the attitudes of pre-hatching life (1932d). This same observation, incidentally, although too infrequently presented, can be made in respect to mammals and man, and as such will do much to explain the maturation of many allegedly saltatory behavior patterns of postnatal life.

Gottlieb and Kuo (1965) have recently published an extensive study of the development of the embryo of the Peking duck (*Anas platyrhynchos*). In this study the techniques described previously for research on the development of behavior in the chick before hatching were used. In these experiments the air space was shifted from the blunt end of the egg to allow the opening of a window for the study of embryos of less than 12 days of development. The stages of development noted above for the chick were also found in general as characteristic of the duck. The cited paper gives precise details concerning amnion contractions, heart-beat, passive and active head movements,

eye movements, oral movements, neck movements, wing movements, hindlimb movements, tail movements, hatching movements, vocalization "combination movements," and responses to external stimulation. The authors stress the role of self-stimulation in the facilitation of motor patterns in the duck. They say, "there is as yet no evidence to show that conventional learning theory is relevant to the prenatal development of behavior." They quote Thorpe (1956) "What is happening inside the egg when we detect movements of the embryo is, mainly if not entirely, a process of maturation of the innate behavior patterns." Gottlieb (1965) has also demonstrated that chickens and ducks have prenatal auditory sensitivity and chicks and ducks soon after hatching respond to the maternal call of their own species better than the maternal call of the other species.

In a recent book, Kuo (1967) stresses the complexity and variability of behavior at all developmental levels and introduces the concept of behavioral gradients and the concept of behavioral potentials.

In the carrier pigeon Tuge (1934) has shown that active movements as opposed to passive movements begin at about 105 hours after the beginning of incubation. The first movements observed are extensions and flexions of the head. In 10 additional hours muscles of the neck, trunk, rump, and tail are also involved. "Spontaneous" movements begin before response to chemical or tactile stimuli can be evoked. At about 125 hours in the incubation period the first flexion of the head and neck to tactile stimulation is called out. The reflexogenous zone spreads from the cephalic to the caudal region as development proceeds. Local reflexes of the wings and legs appear at about 155 hours.

Orr and Windle and then collaborators (Orr and Windle, 1934, Windle and Orr, 1934a, Windle and Baiccroft, 1938, Windle and Nelson, 1938, Windle, Scharpenberg, and Steele, 1938) have studied in detail the development of the bird. In 1934 Orr and Windle reported that the first response to a blunt vegetable fiber needle takes place in the embryonic chick at 6½ to 7 days after the onset of incubation. This first response is a quick movement of the wing away from the trunk, a lateral flipperlike extension. This

movement remains localized. The local reflexes of the embryo do not seem to develop from a generalized behavior pattern but rather arise independently. In another paper (Windle and Orr, 1934a) these two investigators show that the flexion of the chick fetus which takes place on the fifth day is of a sort which cannot be explained by the spinal cord structure at that time. Probably the mechanism that sets off this behavior is chemical in nature. The motor and sensory sides of the nervous system develop independently of each other, and the motor side is functional first. For a detailed report of the neural structure of the chick as its behavior develops, the reader should consult Windle and Orr's paper (1934a). Windle and his collaborators (Windle and Barcroft, 1938, Windle and Nelson, 1938, Windle, Schapenberger, and Steele, 1938) have also published a series of papers upon the initiation of respiration and the development of respiration in the duck and the chick. Peters, Vonderahe, and Powers (1958) have studied by electric means the development of the eye and optic lobes in the chick embryo.

Kuo has also developed an elaborate theory of the growth of behavior in relation to environmental factors. He points out that the intensity of stimulation must be controlled if one is to make any statement concerning the generality or specificity of an organism's response. He has pointed out that the physiological and behavioral growth of the organism may be summarized in ten stages: (1) cardiac movement, (2) active head movement, (3) trunk movement and response to electric currents, (4) first limb and tail movements and first amnion contraction, (5) head turning and lateral flexion, (6) the hyperactive period from 6 to 9 days, (7) reduction of bodily activities, (8) period of relative quiet (15 to 18 days), (9) pre-hatching stage, (10) hatching behavior (Kuo, 1938). This is a descriptive procedure much preferred to any too easy generalization attempting to summarize the whole course of behavioral growth. Kuo (1939b, 1939c) has also given an interesting review of the whole question of which comes first, total patterns or local reflexes.

As previously suggested, the possible importance of chemical mediation in the determination of the onset of behavior requires

study. Kuo (1939a) published a paper summarizing his investigations in this field.

Oppenheim (1966) has demonstrated that the removal of the amnion on days 9, 10, and 11 has no effect on the cyclic motility of the chick embryo. These observations lead us to question the importance of amnion activity in the initiation and maintenance of cyclic embryonic activity at the ages studied.

It has previously been noted that some birds are far advanced at hatching; these are the so-called precocial birds. Such birds, as soon as they are out of the shell, are ready to be acted upon by the new external environment in very specific ways. In recent years the term *imprinting* has been applied by ethologists and other students of animal behavior to a rapid acquisition of behavior that commonly occurs early in life (or at some *critical period*) and that is relatively immune to extinction or forgetting. Lorenz (1935) points out that imprinting can be seen very clearly in the following of the mother or some other moving object by newly hatched birds. This is said to be a condition where the motor responses are innate and ready soon after hatching but the "releaser" (effective specific environmental stimulus complex) is not innate. Lorenz says that this process of imprinting is basically different and cannot be identified with learning. But this question is an involved one and is clearly and exhaustively considered by W. Sluckin (1964) [See also Schiller (1957), Gray, (1963), and Moltz (1960 and 1968)].

The idea of imprinting is not new. It was clearly described by D. A. Spalding (1873) in an epoch-making paper. The present writer made reference to this work in 1925 (Carmichael, 1925). Spalding's research was, indeed, discussed in some detail in James' *Principles of Psychology* (1890).

W. Craig (1914), one of the present writer's teachers, early pointed out another form of imprinting that has since been more completely studied. He notes that ring doves removed from their parents at a young age directed sexual responses at 1 year to the hand of the experimenters and at first ignored female doves as objects of courtship. The previously isolated doves still reacted positively to the human hand even after normal sex behavior had been established (See also Craig, 1908).

H F Harlow and his associates have made dramatic and important discoveries concerning the development of infant-mother affection, mother-infant affection, peer affection, heterosexual affection, and parental affection. These are put through an orderly series of maturational stages (Harlow and Harlow, 1965).

Other examples of the importance of maturation and of early experience or imprinting on courtship, aggression, and anxiety have been described. Much of this work is summarized by Beach and Jaynes (1954). Andrew (1964) has shown that "naive" day-old chicks can be caused to respond to objects in their environment when these chicks were injected with testosterone and kept in isolation until tested. Two of the chicks at once mounted the imprinting object and carried on copulation movements after their first approach to it. Other papers which describe the effect on the time of appearance of specific behavior patterns by the injection of testosterone in chicks can be reviewed in this connection.

Many experiments have been carried out, especially on nidifugous birds, to study the imprinting of a following response. Fabricius (1955) has studied this in detail. E. Hess has shown in excellent laboratory experiments that when ducklings are hatched, the first moving object they see is ordinarily the mother duck. Thus the young, immature animals will typically follow her, but if they see another moving object, they will follow it (Hess, 1958, 1962). Jaynes, in a series of papers, has studied the interaction of learned and innate behavior with special reference to imprinting and emergent discrimination (Jaynes, 1956, 1957, 1958a, 1958b). See also Moltz (1960, 1968).

The fact that birds can be imprinted by sound has been shown by Grier, Counter, and Shearer (1967). A batch of eggs was exposed to a patterned sound continuously from day 12 to day 18 of incubation while a control group was hatched in quiet. In a postnatal test, all chicks tended to creep toward a stationary sound source but the experimental group showed a preference for the sound heard during incubation. In a second test, the experimental chicks followed a moving model longer when it emitted the familiar sound than when it emitted a novel

sound or no sound at all. These results indicate that imprinting follows the law of anticipatory function as defined previously.

THE DEVELOPMENT OF PRENATAL BEHAVIOR IN THE INFRAHUMAN MAMMAL

The development of behavior in the infrahuman mammal is in a number of respects more significant for one who would understand the growth of behavior and psychological functions in man than is the consideration of the amphibian or bird presented above. There are peculiar difficulties, however, in studying the development of fetal behavior in mammals. These difficulties can be made clear only by a brief review of the bodily structures and functions involved in the prenatal development of typical placental mammals, including man. In barest outline, disregarding many differences between various species of such mammals and many consequent qualifications, this process of development may be reviewed as follows.

The tiny fertilized mammalian egg is not at first attached but, probably as a result of ciliary action and the muscular contraction of the tubes, moves from the oviduct where it has been fertilized to the uterus. Parker (1931) has summarized the evidence in this field. During the process of movement, which occupies 4 to 10 days, depending on the type of mammal under consideration, the processes of development have begun which are to form the embryo and its membranes. Two embryonic folds are early formed which join to make up the then enclosing amniotic sac. This sac gradually enlarges. It is filled with a special liquid, the so-called amniotic fluid, which has a very definite chemical make-up and a specific gravity of 1.006-1.081 (Feldman, 1920). The specific gravity of this liquid is thus not far from that of the developing embryo, a fact of great importance in understanding the mechanics of certain forms of receptor-nervous-system-effector action in the fetus at a later period. That there is a change in the specific gravity of the fetus during development has been shown by Stephenson and Roberts (1962) in the sheep at 50 days it is 1.03 but at 140 days, about 1.06 (Stephenson and Roberts, 1962). As growth continues, the sac more

and more completely surrounds the embryo

It is quite appropriate, as numerous writers have pointed out, to compare the "weightless condition" of the mammalian fetus with the traveler in space. It will be emphasized later that because of this condition, the fetus shows many types of behavior that are not observed for some time after birth. Reynolds (see Avery, 1965) says, "It is a captivating thought that the uterus is the assigned space capsule of mankind and that all have been, so to speak, in weightless orbit—before they were born." Avery discusses this idea from a physical and psychological point of view in some detail.

The embryo thus immersed and supported is relatively independent of most direct mechanical surface contacts. Coincident with this development the other fetal sacs are formed. One of these, the vitelline sac, corresponds to the yolk sac of lower forms, although of course in the higher mammalian types it contains virtually no yolk. In later development of the fetus this sac is relatively much reduced in size, and at the time of birth is known as the umbilical vesicle. Snell and Stevens (1966) have given an admirable description of the early embryology of the mouse. Sections of embryos spaced at 6-hour intervals from 4 to 9 days were used in the study. The diagrams and reproduced sections make this treatment very clear and the authors also give full citation of relevant literature.

Now that so much attention is being given to organ transplants in adult human beings, it is interesting to think that the fetus is in a sense a foreign organism that has a different genetic code from the mother and yet is a successful graft. If the factors influencing this "graft" could be understood it might be more easy to improve the steps now used in heart or kidney grafts.

The allantois also makes its appearance as an outgrowth of the developing digestive tract of the embryo. This saclike structure comes in contact with the previously formed primitive chorion, with which it fuses to make up the true chorion. This doubly derived chorion now rapidly becomes a completely enclosing membranous wall outside the amniotic sac. The chorion continues to be attached to the embryo proper, however, by means of the allantoic stalk, which comes

to conduct as well the two allantoic arteries and the two allantoic veins.

As this development has progressed, therefore, the mammalian egg has become attached to the wall of the maternal uterus. As the very complex morphological changes, some of which have been suggested earlier, take place, the circulatory system of the fetus and its membranes continues to develop. This fetal circulatory system is mechanically completely separated from the maternal blood system, but the separation is, in certain areas, only that of a cell wall. By interchange through living membranes, therefore, oxygen and food materials pass from the maternal blood system into the independent embryonic blood system, similarly, carbon dioxide and other metabolites pass in the opposite direction into the maternal blood stream. Some antibodies, blood components, proteins, and other substances also pass the placental barrier. Typically, in the higher mammals only part of the chorion is directly attached to the maternal uterus. This area of attachment is called the placenta. As noted later in the chapter, the exchange of endocrines through the placenta is important. The placenta may best be thought of as involving two parts, one derived from the embryo and the other from the maternal uterus. The part derived from the maternal uterus becomes larger and larger, eventually encapsulating the developing embryo and its membranes, which have just been described. This true maternal membrane, as distinguished from the previously considered fetal membranes, is called the *decidua capsularis*.

In human development, as the fetus grows this *decidua capsularis* comes to be in contact with the mucous membrane lining of the rest of the uterine cavity, the so-called *decidua vera*. Thus as it grows the fetus is enveloped in an elaborate series of membranes. Figure 4 shows these relationships in very schematic form in the human organism. These developed membranes serve an important function. They provide within the mother's body a strong, many-layered sac in which is maintained a liquid environment of very constant temperature and remarkably constant physical and chemical constitution. Hsu (1948) has shown that in white rats increasing the temperatures somewhat above normal affects pregnancy. The results

Fig 4 Diagram representing the relationship between the uterus, the membranes, and the embryo during early pregnancy (From Carmichael, 1933)

suggest that with elevated temperatures the percentage of pregnancies affected is greater when the heat treatment is earlier. This result emphasizes the importance of constant and normal conditions of the uterus during pregnancy.

For an elaborate consideration of fetal development made clear by excellent diagrams, see Spee (1915). See also Barclay, Franklin, and Pritchard (1946, 1947) for a consideration of changes in fetal circulation at birth (See also Stang, 1964).

By means of the association at the placenta, as just noted, the independently developing embryo is able, parasitically as it were, to receive food materials, oxygen, and other substances from the maternal blood supply and to send back into that system the waste products of its own organic life. The extremely important and technical topic of fetal respiration has been intensively studied by Barcroft and his associates and by many other workers. For a review of this literature see Barcroft (1938, 1946) and Windle (1940). The mechanism of the fetal membranes, therefore, makes possible fetal respiration, nutrition, and excretion. It is in a physical world of this sort that we must consider the fetal mammal as developing and in its later stages as actively responding. The nature of this very special environment must

not be forgotten in considering every evidence of sensory or behavioral life which the fetus shows. It must be emphasized, however, that there are great differences in detail in the relationship between fetus and maternal organism in different mammals. As Windle (1940) has pointed out, "Time and again in the study of prenatal physiology it will appear that species variations in the intimacy between maternal and fetal blood streams may explain differences in experimental results."

The relationship between blood flow in the umbilical cord and the rate of fetal growth in the sheep and guinea pig has been studied by Greenfield, Shepherd, and Whelan (1951).

The rupture of the fetal membranes during parturition is produced by the contractions of the muscular walls of the uterus. The physiology of this process is complex and important (See Barron, 1940).

Parturition and birth are important processes in the life of every mammal. The word *parturition* is derived from the Latin and means "in labor." It is a name for the actions and processes of the mother that lead to the giving of birth to offspring. The word *birth* is a name for the processes in the period during which a mammalian fetus becomes established as an individual that is physio-

logically independent of the mother's body

One of the most important physiological facts of birth is the change from fetal circulation to postnatal circulation. This involves the closing of the foramen ovale (the fetal opening between the two auricles of the heart) and the ductus arteriosus (the short vessel in the fetus which connects the pulmonary artery with the aorta). In some human neonates known as blue babies (i.e., babies with congenital cyanosis) the fetal circulation persists to some degree and may require surgical intervention. No one can fully understand either fetal or neonatal responses without realizing the great importance in the release of such behavior of the adequacy or inadequacy of the supply of oxygen to the brain (See Barcroft, 1938, 1946, etc., also W. F. Windle, 1940).

A new book, *Fetal and Neonatal Physiology*, by G. S. Dawes (1968) considers in detail the development in the fetus and in the newborn organism of the structure, functions, and responses that are necessary to maintain the normal internal environment and to allow growth and development. Here the modern literature on fetal circulation, birth changes, and the circulation of the blood in the newborn are fully considered. The comparative "critical periods of development" for the brain of man and other mammals is well considered in this volume.

A short time after the birth of the young mammal or the child there follows the expulsion of the now discarded enveloping membranes. This "afterbirth" consists largely of the remains of the decidua, the chorion, and the amnion. In infrahuman mammals this afterbirth is customarily eaten by the mother (Tinklepaugh and Hartman, 1930). This is an interesting response to be considered in relation to the problem of the special hungers and patterned "instincts" of the organism.

There are those who advocate in human birth draining the blood of the afterbirth into the newborn child.

From what has been said, it is obvious that the developing mammal is so well protected that it is difficult to study its growth at different periods, and nearly impossible—although the "impossible" has been accomplished, as will be pointed out later—to observe continuously the development of the

same mammalian fetus. A series of papers by Nicholas (1925, 1926, 1927, 1929a) demonstrates the possibility of experimental manipulation of the mammalian egg and growing embryo. This work has fundamental implications not only for the "new" embryology but for the whole study of the growth of behavior.

It may still be said that it is "impossible" to study the mammalian fetus under as nearly normal conditions as those under which Kuo has studied the chick. There is real danger in generalizing upon the nature of fetal development on the basis of observations made under abnormal conditions, as Kuo himself (1932c) has said. Observations on the mammalian fetus must be abnormal because the protection which is provided by the fetal membranes just considered must be destroyed if some forms of direct observation are to be possible.

It will, of course, be unnecessary here to give an account of the development of behavior in all classes and orders of mammals. Indeed, no special studies have been made of most mammalian forms. For example, so far as the writer is aware, no special study has been made of the development of behavior in the fetal monotremes. The study of the development of behavior in these primitive Australian egg-laying mammals would probably provide fundamentally significant facts that might be applied to higher, truly viviparous forms. In both the ornithomylid and the echidna, eggs with soft shells, rich in yolk, undergo segmentation in the uterus and are then laid and incubated. The incubation by the ornithomylid is in a nest, by the echidna, in a pouch. When hatched, the young of this subclass are nourished by the secretion of great glands possibly more like sweat glands than like the true mammary structures of higher mammals. But a detailed description of behavioral growth in these forms is not, so far as the writer can discover, available (See Buell, 1927).

Study of the development of behavior in what is generally considered the next higher subclass above the monotremes—namely, the marsupials—has been carried on. Indeed, the marsupials are found to be very favorable material for developmental studies. The young of animals in this subclass

are born in a condition which can be considered only that of a relatively immature fetus (Langworthy, 1928). In the marsupials, although early development occurs in the maternal uterus, and although the fetus is nourished by secretions from the uterine wall, no true placenta is formed. Possibly for this reason these true mammalian fetuses are born while still at an early period of development and are as yet open to easy continual external observation during most of the important growth stages in which behavior change may be noted. This fact has made this form a favorite one for studies of neurological development by such students as Weed and Langworthy (1925a, 1925b) and Langworthy (1928). After birth the young are cared for by the mother for many weeks in a pouch, the marsupium, into which the mammary nipples open (Hartman, 1920). In certain of the marsupials, indeed, the once independent fetus again becomes functionally but not structurally attached to the mother, as for a long period after the maternal nipple is taken into the mouth the nipple is never removed until the animal is ready to enter upon truly free life (Hartman, 1920).

From the standpoint of the student of the development of behavior, the most adequately studied form of this subclass is the Virginia opossum. In a series of complete and brilliant papers, Hartman (1916a, 1916b, 1919a, 1919b, 1920) has brought together the knowledge in regard to the development of the fetus in the opossum and related types. Until his own work was begun, Hartman points out that the birth of the opossum and the behaviorally significant journey of the newborn organisms to the pouch had been observed and described by but one man, Middleton Michel. Michel's observations, which are reprinted by Hartman (1920), led to a belief that the mother transferred the newborn animals to the pouch. Hartman's work, however, has shown that the newborn organisms travel directly from the vulva to the maternal pouch without the aid of the mother. He says:

Unwillingly the embryo traveled by its own efforts, without any assistance on the mother's part, other than to free it of liquid on its first emergence into the world, this ten-day-old

embryo, in appearance more like a worm than a mammal, is able, immediately upon release from its liquid medium, to crawl a full three inches over a difficult terrain. Indeed, it can do more after it has arrived at the pouch; it is able to find the nipple amid a forest of hair. This it must find—or perish.

Hartman has further shown that this essential journey is to be considered a negative geotropism, because under experimental conditions embryos can be made to travel away from the pouch if only the skin upon which they are moving is tilted upward. The locomotion of the embryo is described as a kind of overhand swimming stroke in which the head sways as far as possible to the side opposite the hand which is taking the propelling stroke. It is further noted that "With each turn of the head the snout is touched to the mother's skin and if the teat is touched, the embryo stops and at once takes hold."

The conclusion may be suggested, therefore, that this young mammalian organism, less than 2 weeks removed from an unfertilized ovum, has already developed to a point of independent ability so far as an respiration, alimentary canal digestion, and the receptor-neuromuscular mechanism of geotropically oriented simple progression are concerned. McClady (1938) has devoted a book to the description of the development of the opossum, a notable book in many respects but especially because of its beautiful drawings.

McClady, Weaver, and Bray (1937) have studied the electrical responses from the cochlea of the pouch-young opossum. These investigations have correlated reflex startle responses and the electrical output of the ear. The first responses of a startle type were found at 50 days. Nine days later the electrical output showed that the sensitivity of the ear was in about the midaudible range with 2000 cycles as the maximum. At 82 days the maximum had shifted to 7000 cycles. A linear relationship between intensity of stimulus and electrical response was found. This suggests that these young organisms have a very efficient electrical-acoustical apparatus. Hill and Watson (1958) have described the early development of the brain in a number of marsupials. The development of tempera-

ture regulation in the opossum has been described by Petajan and Morrison (1962)

Goeling, in an article also republished by Hartman (1920), gives an account of the birth of the kangaroo, an animal of the same subclass as the opossum. It has been observed that in the kangaroo the young animal moves through the fur from the opening of the urogenital canal to the pouch. The following observation is recorded in regard to the fetus: "It moved about slowly, very slowly, through the fur upwards, using the arms in its progress, and continually moving the head from side to side." (Hartman, 1920) Thirty minutes were required for the passage, but during this time the mother gave no assistance whatsoever. Goering further notes that the arms of the newborn kangaroo are strongly developed. The small hands open and close like a cat's paws. He says "By these strong little arms and hands the young one is enabled to labour its way to the pouch, the place of safety and nourishment" (Hartman, 1920). It is further pointed out that, so far as the sucking reflex is concerned, once a young kangaroo is removed from the teat which it has taken in its mouth it is apparently unable to reattach itself. Figure 5 shows the early fetal appearance of the pouch-young kangaroo (Parker and Haswell, 1921).

In the series of papers referred to above, Hartman reports his studies of the early embryology of the opossum but without any detailed reference to the onset and development of behavior before the early motility stage in which it is found at birth. It is interesting to

Fig 5 A so-called mammary fetus of the kangaroo attached to the maternal teat (From Parker and Haswell, 1921)

note, however, on the basis of the evidence given above, that in the marsupials young organisms which might even still be called embryos are born in what is in many respects a very early fetal condition. Their behavior, as indicated above, is significant at any rate in a number of ways for the general student of the development of response. Once in the pouch these organisms can be studied without the usual difficulties of disturbed respiration and digestion of higher mammalian fetuses of comparable developmental age which still depend upon the placental circulation. The reports just given suggest that in this organism there is a general conformity with the pattern of development of the amphibian larvae considered previously. As in the case of *Amblystoma*, the young opossum moves with a wriggling movement which from the description, "the head swaying as far as possible to the side opposite the hand which is taking the propelling stroke" (Hartman, 1920), suggests the double S movement elaborated by Coghill and others as a characteristic of the onset of aquatic locomotion in larval amphibians. It is also significant to note that it is the forelimbs, both in the opossum and even in that characteristically hindlimbed organism, the kangaroo, which are mentioned as the first effective agents of locomotion.

This again at least does not contradict the view that behavior typically develops from the anterior to the posterior segments of the organism. This generalization may be said to be essentially true of behavior growth in invertebrates, amphibians, and bird embryos. Moreover, there is nothing in the development of the feeding reaction which is presented that shows its essential sequence to be different from that already noted in lower types. Langworthy (1925, 1928) and Weed and Langworthy (1925a, 1925b) have studied the development of progression and body posture in pouch-young opossums. They find that decerebration of young opossums does not lead to decerebrate rigidity, but rather to an increase in progression movements. This suggests that at this period the cortex has as yet established little dominance over the other neural determinants of behavior. Similarly, they note, after giving a complete review of the work on the nervous system of the opossum, that electrical stimulation of the brains of pouch-young opossums gives contralateral

leg responses but no other responses for over 50 developmental days (Weed and Langworthy, 1925b). These observations are important in regard to the part played by myelination of the nervous system in behavior and, incidentally, seem to confirm the priority of forelimb progression in the early behavioral repertoire of this form. Laisell, McClady, and Zimmerman (1935) have studied the morphological and functional development of the membranous labyrinth of the inner ear of the opossum. Nerve endings are present around the receptor "hair cells" before the ear is functional. Vestibular reflexes appear at about 43 days after insemination, acoustic reflexes appear at 50 days. Myelin appears on the vestibular nerve fibers at the time reflexes first appear. It increases as the reflexes become more pronounced. The evolution of marsupial reproduction is clearly treated by Kean (1961).

Of all orders of infrahuman mammals, the rodents have probably been most completely studied, so far as the development of behavior is concerned. It is difficult to say when the study of behavioral growth in rodent fetuses began. They are convenient animals to work with, and it is highly probable that some member of this order was used by the classic embryologists, whose work will be reviewed historically in the course of a discussion of the specific development of behavior in man is given. It is known, at any rate, that the dead embryos of typical rodents—namely, the rabbit, guinea pig, and mouse—besides many other animal forms, were discussed by Hieronymus Fabricius in his monumental work *De Formato Foetu* in 1604 (Needham, 1931). It is highly probable that this writer or some of the other great embryologists of the Renaissance observed the behavior of fetal rodents, because at this time embryology was still much concerned with the Aristotelian problem of the development of the vegetable, sensible, and rational souls in all the forms which were studied.

It was not until Peyer began his series of experiments on fetal guinea pigs and other animals that the modern period of the study of the behavioral growth of the rodent began. In his summarizing work of 1885, Peyer gives an elaborate history of the study of the development of behavior in each form which he considers. Significantly enough, however,

in this treatise, when he deals with the development of mammalian behavior, he begins almost without historical references.

Peyer (1885), in his own experiments, however, used a number of different types of mammals and a number of different techniques in his study of the development of behavior. His most significant work was done on the guinea pig. In studying this rodent he used at least six methods.

- 1 The animal was placed on its back, and the movements of the external abdominal wall of the pregnant mother were observed without interference. He also made such observations on pregnant females on which so-called animal hypnosis or tonic immobility had been induced by an appropriate posture and pressure manipulation. As a result of these types of direct observation he concluded that there are periods of quiescence, lasting sometimes for more than an hour, interspersed with periods of great activity in fetal behavior, at least during the latter part of the pregnancy.

- 2 In another experiment he placed a long, thin needle directly through the abdominal wall and the fetal sacs of the pregnant female and pressed it into the fetus. This needle was inserted so that, when the fetus moved, the needle, forming a sort of lever, could be observed to change its position. As a result of these investigations, the frequency of fetal activity was noted. It is all too clear to the modern investigator accustomed to the use of anesthetics in animal experiments that the fetus and the mother could hardly be considered "normal" during these studies.

- 3 He listened to the fetal movements through a stethoscope and recorded that in the later stages of pregnancy they made a peculiar *Knustern* and *Knacken*.

- 4 By operation he found it possible to allow a single limb to extrude from the sac in such a way that its movement could be observed.

- 5 By experimental surgery it proved possible to observe the movements of the fetus still in the mother's body. In this situation he was able to note the effect of changing the blood supply upon fetal behavior and to come to the conclusion that, although deprivation of oxygen did at times lead to general fetal movements, such deprivation was not an essential cause of such movements.

6 He also removed guinea pig fetuses in the air-breathing stage and studied them when supported by blood-warm physiological salt solution and in a warm chamber. In observing the movements of such fetuses he characterized their responses as "*schr mannigfaltig, ungeeignet, asymmetrisch, anhythmisch*"

It is interesting to note that these are virtually the same words used by Minkowski and many others later in describing early human fetal movements. Preyer also observed certain movements of stretching and of reflex contraction and extension which would be difficult for the fetus while confined in the sac. This phenomenon has been seen many times by the writer, who knows of no evidence that Preyer used any anesthetics in employing any of the methods noted above. The criticism of the more painless work of later investigators, that possibly the fetal material was anesthetized, cannot therefore be urged against this pioneer work of Preyer, which may, however, be criticized on humane grounds.

In one case Preyer (1882) notes that, when his observations were made on a guinea pig in the still intact sac, touching the skin of the face led to a localized brushing movement on the part of the forelimb of the fetus as if to wipe away the offending stimulus which was touching the pad of the vibrissae. We shall see that the study of the development of this ability in the fetus may throw light upon certain aspects of the old question as to whether or not the perception of space is natively or empirically determined.

Preyer gives a rather general description of development in the fetal guinea pig. In a fetus 20 to 21 mm in length no movement was seen, but he adds that this may not be interpreted as assurance that no movement had previously occurred while the organism was in the uterus. In one of 81 to 83 mm, however, opened under blood-warm salt solution, the heart was seen to beat strongly and chest movements were noted. In much larger fetuses, 105 to 111 mm long, a complete repertory of action almost like that seen in the adult animal was recorded. Many other observations are given on fetuses whose lengths are not recorded. On the basis of these observations on fetuses, often approximately dated by statements in regard to the hair and

teeth condition of the organism, it is possible to say that Preyer noted in the development of behavior in the guinea pig a gradual change in response with growth. The very early movements changed by gradual development until elaborate adaptive responses appeared. Concerning a series of carefully weighed litters in later stages he gives a detailed account of definite responses. These activities include the pinna reflex to sound, now often called *Preyer's reflex*, the pupillary reflex to light, and even the cerebral inhibition of reflexes as a result of antagonistic stimuli (1885). He points out that in a 173-gm guinea pig the teeth of the organism were so well developed that they bit his fingernail sharply. On the basis of all this observational and experimental work, Preyer turns to his consideration of the development of behavior in the human fetus, to which reference is made below.

The first systematic study of the development of fetal behavior in guinea pigs, from the point of view of behavioral psychology, is Avery's (1928), carried out in the Psychological Laboratory of Stanford University. As a background for the study of prenatal development, Avery carefully investigated the responses to stimulation shown by newborn guinea pigs (See also Diaper, 1920). As contrasted with the naked and almost helpless neonatal marsupials described previously, the guinea pig is at birth in many respects structurally and functionally a mature animal. It is born with a sleek coat of fur. Its teeth are well erupted. Its eyes and ears are open. Its heart pulsations and breathing may be quite continuous and regular. It is able to roll from back to side, side to back, and side to haunches. It can crawl, stand, and walk.

To the pinch stimulus applied to the foot it responds by kick or withdrawal of foot. The electrical stimulus elicits a muscular twitch, respiratory gasp, and jump. It can execute the scratch reflex spontaneously or when stimulated in the facial region. Although muscular weakness is evident the patterns of response show good coordination (Avery, 1928).

The sensory control of behavior, this investigator points out, has also progressed to a remarkable degree. Lid and pupillary reflexes are present. The newborn animal avoids objects without touching them as it moves about

The ears are functional, and total bodily movements and pinna twitches are elicited by appropriate auditory stimulation. Needle pricks and heated objects lead to quick response. Olfactory stimuli evoke movement of the head. The complex movements of swallowing are well developed. So far as more integrated behavior is concerned, Avery reports that the young run together when separated from each other and run to the mother when separated from her. Somewhat similar observations were also made by Preyer (1882). The young lick themselves, swim when placed in deep water, chew shavings, and attempt to disengage a foot held by an observer. No retreat responses were noticed when young guinea pigs were placed with an adult white rat. The prenatal development of behavior of this *Mineiva*-like organism is therefore peculiarly interesting because it is such a complete story.

Avery's work on prenatal development must be strictly evaluated, however, in terms of the rather special conditions which he employed in his experimental study. Abandoning the techniques used by some of the earlier investigators in mammalian behavioral development, Avery removed from the mother each fetus that he studied. He thus, of course, intercepted placental circulation and therefore brought about all the changes which have been found to result from oxygen deprivation and an increasing concentration of metabolites in the fetal blood stream. He often worked with dying fetuses. Thus his work is strictly comparable to most of the work on human fetuses reviewed below. Observations were most often made on a large metal tray placed on a well-lighted observation table. "An electric heater, reflector type, was placed nearby. It served to dry the young and to keep them warm. A temperature of 98° F. was maintained on the observation table" (Avery, 1928). This technique provided that, so far as early embryos were concerned, they were studied not only without normal respiration but in what was apparently a continually diving condition.

Avery also considered the question of whether or not there is a distinction between the responses of fetuses taken from young and old mothers. He came to the conclusion that there is no significant difference in the maturity of response elicited from the fetuses of young and fully adult mothers. This conclu-

sion is unlike that of King (1915) and of Angulo y González (1932b) in regard to the white rat, in which various parental conditions were found to influence fetal development.

By the use of X-rays Avery also ingeniously studied the orientation of the fetuses in the uterus of the guinea pig. This study convinced him that gravitation is apparently not very significant in determining rapid changes in the orientation of the fetus in the uterus. He concludes "The shifts of the fetuses in utero are inadequate to explain their activity after experimental delivery." As a final conclusion to his study Avery says "These results substantiate the belief that certain congenital response mechanisms exist in foetal and newborn guinea pigs. Some of these are subject to early modification through experience." For an interesting early study in this field, see Vney (1833).

Carmichael (1934a) studied a large number of fetal guinea pigs in a series of experiments in which as many factors as possible were controlled. This study involved more than 2 years of work and the typing of more than 2000 pages of protocols dictated at the time of the experiments. In most cases motion-picture records of behavior were also made. The apparatus used is shown in Fig. 6. A summary of results follows.

- 1 Heartbeat was the only activity observable in the youngest fetuses studied in this investigation.

- 2 Before any behavior was observed the skeletal muscles of the still immobile fetus could be made to respond by direct electrical stimulation.

- 3 In a 28-day fetus behavior involving skeletal muscles response without electrical stimulation was observed.

- 4 The first "spontaneous" movement observed was a lateral flexion of the neck and a synchronous and possibly independent movement of the forelimbs.

- 5 The first sensory area from which behavior was released in the present study was the concha of the ear.

- 6 In general, responses at every stage are a function of what were called (a) modes of stimulation and (b) variable conditions of the organism.

- 7 The first stimulus-released response noted

Fig 6 Photograph of apparatus (1) Constant-temperature tank in which is inserted a tray filled with physiological saline solution. Maternal animal is held in this bath by suitable supports and fetal organisms are then exposed for study (2) Holder and graded series of esthesiometers (3) Electrically driven motion-picture camera for recording (4) Reflectors for two 1000-watt lamps used to illuminate the field (5) Foot-operated switch to start and stop the recording motion-picture camera (From Carmichael and Smith, 1939)

in the study may be characterized, at its first appearance, as a pattern of behavior, which involves a relationship between neck flexion and forelimb movement

8 Many of the points indicated when stimulated, release behavior from the fist which in spite of very great variability could always be considered as a special "pattern of behavior"

9 Each behavior pattern released by the stimulation of a particular area may be said to undergo a series of changes during fetal life

10 Photic stimulation of the eye may lead to motor responses of the limbs, etc., before the eyes are normally open in the fetus, when such stimulation is made possible by an operative exposure of the eye

11 Auditory stimuli released behavior in a 63-day fetus after the liquid had been removed from the external meatus

12 Needle stimulation ("pain stimuli") in general released responses which were quite comparable to responses released by pressure stimuli rather than to the vigorous responses characteristic of the adult animal when subjected to pain stimulation

13 Temperature stimuli well above and well below the temperature of the fetus, when applied to the skin, release behavior

14 In late fetuses compensatory movements during rotation and in the immediate post-rotational period were demonstrated

15 There is evidence that in late fetal life higher brain centers influence responses which are characteristically called "spinal reflexes"

16 As development progresses, the amount of "motor diffusion resulting from specific receptor stimulation" decreases, at least in certain areas and under certain stimulus conditions

17 The study does not confirm in detail

the specific laws of development, alleging that development is in all respects cephalocaudal, proximo-distal, or from "fundamental" to "accessory" muscles

18 It is possible to view most of the typical patterns of behavior released by the stimulation of given areas as capable of securing some end or ends, which during fetal life itself or during subsequent independent life may serve adaptive needs of the organism

19 The present study does not give unqualified support to any of the more general theories of the development of behavior, such as those summarized by the words "individuation" or "integration"

After this general study it became apparent that a more detailed study of certain aspects of fetal behavior in the guinea pig was important. Bridgman and Carmichael (1935) studied 47 fetal litters *at just about the time that behavior first begins*. As a result of this study the following conclusions were drawn:

1 Prior to the onset of behavior in the fetal guinea-pig, myogenic contractions can be elicited from certain muscles. That these early responses are truly myogenic, and not sensory-motor responses, there is little doubt, because of their character, particularly as compared to later movements.

2 Active behavior in the fetal guinea pig begins in the last hours of the twenty-fifth day. Previous observers had placed the onset at least 1 day later than this.

3 True behavior, that is, response that results from stimulation, and which is secondarily induced by nervous discharge, can be elicited 10 to 14 hours before "spontaneous" behavior appears. These stimulated responses are of a sufficiently different character from the earlier myogenic contractions to be classified as active, i.e., involving neural activity.

4 The first active responses of the fetal guinea pig are definite in character, and involve movements of the head, brought about by contraction of the neck muscles, and of the fore leg. The evidence is as yet inconclusive concerning which of these components arises first.

5 It is seen that, from the earliest period, the neck and limb responses occur sometimes together, and sometimes independently, and that throughout the developmental period

studied, independent elements of behavior are present at all times. That is, no gradual progressive "individuation" of the specific responses out of a total pattern is seen.

6 Because of the simple and specific nature of much of the earliest behavior of the fetal guinea pig, it is thought that these responses may advantageously be described as reflexes. Moreover, no need to use such words as "generalized," "totally integrated," or "non-specific" in the description of this behavior has arisen.

The development of temperature sensitivity in the fetal guinea pig has been studied by Carmichael and Lehner (1937). The results of this study are summarized in Fig. 7. This figure shows that in fetuses of all ages there is an increase in released behavior as stimuli (drops of water) are used which are either warmer or cooler than the physiological zero (about 37.5° C) of the organism. The conclusions of this study may be summarized in the following statements:

1 Temperature stimuli are effective in releasing responses during most of the motile fetal period of the guinea pig.

2 At each of three fetal development periods, as these periods were established for the purposes of this study—young, mid, and old—the greater the difference between the temperature of the stimulus and the physiological zero of the organism, the greater the relative number of responses released by that stimulus.

3 At the youngest ages studied, there appears to be a slight tendency for cold stimuli

Fig. 7 Response of guinea pig fetuses to thermal stimuli. (From Carmichael and Lehner, 1937.)

to be relatively more effective than warm stimuli if certain assumptions of equality are made concerning units of measurement

4 During the "young" period of fetal life, as defined above, there appears to be development of temperature sensitivity. Sensitivity is greater, that is, in the mid period studied than in the initial period. There is no corresponding increase during the other periods studied. In the last period, the growth of the insulating hair coat unquestionably modifies the effectiveness of the stimuli as applied in this investigation.

5 There is no great change in the percentage of specific and general responses released by the stimuli used at any of the three periods studied, nor does the effective intensity of stimulation (as measured by the greater degree of difference from physiological zero) change in a definite manner as development progresses in its efficacy in releasing either general or specific responses. There is a slight preponderance of specific over general responses, as these two words are defined in this paper in each period, but this finding can hardly be considered as statistically significant.

6 There is some shift in the relative sensitivity of the six areas stimulated during fetal development. These data may be considered as supporting the generalization made by previous investigators that the development of sensitivity spreads from the cephalic to the caudal regions of the body and from the prox-

Fig 8 Typical reflexogenous zones (1) Midpoint of the vibrissae pad on the snout (2) Inner surface of the vestibule of one external naris (nostril) (3) Midpoint of the upper eyelid (4) Midpoint of the lower eyelid (5) Midpoint of the concha of the ear (6) Skin over the shoulder joint of the pectoral girdle (7) Skin over the hip bone joint of the pelvic girdle (8) Anus (9) Point in medial plantar surface of one hindpaw (10) Point in medial palmar surface of one forepaw (From Carmichael and Smith, 1939)

Fig 9 Percentage of responses at each fetal age group studied (Normal gestation period 18-68 days) (From Carmichael and Smith, 1939)

Group 35-36 days		
Total responses 275	Light 36.5%	Heavy 63.5%
Group 41-42 days		
Total responses 585	Light 37.5%	Heavy 62.5%
Group 45-47 days		
Total responses 616	Light 33.6%	Heavy 66.4%
Group 50-51 days		
Total responses 730	Light 38.4%	Heavy 61.6%
Group 55-56 days		
Total responses 468	Light 39.7%	Heavy 60.3%
Group 61-62 days		
Total responses 536	Light 35.4%	Heavy 64.6%

imal to the distal region of limbs

Bonardi (1946) has also made observations on the stimulation of the nose with cold and hot water at various fetal ages. At the temperatures used cold water was more effective than hot water in releasing behavior.

Hooker (1944) and other investigators have emphasized the importance of the use of quantified pressure stimuli in working upon fetal material. Carmichael and Smith (1939) attempted to study this question in detail (See also Carmichael, 1937). First they decided to use certain well-established reflexogenous zones as shown in Fig 8. They then prepared a series of calibrated von Frey esthesiometers. In each case the lightest esthesiometer that would elicit a response was used, as well as one 7 to 9 points higher in the scale of esthesiometers. The quantitative conclusions of this study are shown in Fig 9. An example of the difference in response to the light and heavy stimuli is shown in Fig 10. In summary of this study it may be said that pressure stimuli are like temperature stimuli in the importance of intensity upon resulting response.

Fig 10 Outline tracings from motion-picture film of two postures of 51-day guinea pig fetus (a) Resting posture of the fetus as stimulated with light esthesiometer Only response in this case was an eye wink (b) One phase of movement elicited by a heavier esthesiometer In this case, the entire trunk and all limbs are involved in the reaction Note the precise localization of the stimulated spot by the forepaw (From Carmichael and Smith, 1939)

Moreover, the present results show that the same relative proportion of general and specific responses seems to be released at all of the typical fetal ages studied. This finding adds further confirmation to the view that specific responses are early developed in fetal life. Thus it becomes more than ever clear that the widely accepted formula that all specific behavior develops from the individuation of previously more general patterns of behavior needs revision. Such revision can come only from continued study of fetal behavior as released by stimuli of quantitatively known character (Carmichael and Smith, 1939).

Jasper, Bridgman, and Carmichael (1937) have studied the electrical brain potentials of the fetal guinea pig. The conclusions are

- 1 The brain potentials of the guinea pig first appear when the age of 48-56 days of gestation has been attained

- 2 No quantitative ontogenetic trend in the characteristic frequency of potential variation, nor in the total range of frequencies, has been discovered. The appearance of secondary groupings of characteristic frequencies is found more often as age increases

- 3 The average amplitude of the characteristic frequencies at any age shows an irregular but definite increase with age

- 4 Definite though not invariable effects of stimulation on the character of the cortical electrogram have been noted, occurring as early as the 60th day of gestation

- 5 The guinea pig brain first exhibits electrical activity at a time when behavioral indications also point to maturation of higher nervous centers

In connection with this study it was noted that tying off the umbilical cord abolished most cortical activity but did not for some time abolish the lower reflexes of the fetus.

In another study using high-gain electrical amplification of bioelectric phenomena in the fetal guinea pig, Rawdon-Smith, Carmichael, and Wellman (1938) have demonstrated that the cochlear electrical response (the so-called Weaver-Bray effect) is present in a guinea pig fetus of 52 postinsemination days. The electrical response secured at 52 days had a peak voltage of 1 to 2 microvolts to a stimulus of 600 cycles per second at an intensity of 100 decibels above human threshold. Declining responses were noted to tones below this and above 2000 cycles per second. The rise in electrical output was rapid as development progressed, for by 62 days 100 microvolts was recorded. It is interesting to note that the time of onset of the electrical response of the fetal ear—52 days—is exactly the same time at which the first overt behavior released by auditory stimuli can be observed in the fetal guinea pig.

Of all rodents, however, not the guinea pig but the white rat seems to be the most generally studied laboratory mammal. It is not surprising, therefore, that in recent years an increasing amount of attention has been given to the prenatal development of behavior in this convenient organism. One of the most elaborate studies of this sort is reported in an unpublished thesis by Swenson (1926) and in several other papers by Swenson (1925, 1928b, 1929).

Swenson's observation began with fetuses showing absolutely no movement save heart-beat and continued at convenient stages to

both It is difficult to generalize about any such developmental sequence because the omission of any of the details of the onset of behavior is likely to give a prejudiced picture of the total process It is possible in review here, however, to give a few of the salient points of the growth of behavior in the rat as found by Swenson The first movement noticed was a slight lateral bending of the head This same movement, differently interpreted, may be characterized as a slight cephalic trunk-bending movement From this early action to the precise adaptive movements of tongue and paws in late fetuses, there is found a continuous quantitative and qualitative change in the movements as observed in litters of increasing gestation age

Angulo y González (see references in bibliography), also associated with Coghill, has published some very important studies of the development of behavior in the fetal albino rat He used much the same technique as Swenson in operating on the mother rat and in preparing the fetal material for observation He selected his material with unusual care Of the 643 fetuses used in one study, all came from healthy female rats of known stock 110 to 190 days of age, his previous work having indicated that these precautions were necessary in order to obtain scientifically comparable results at various gestation ages In his work moving-picture records were taken to supplement the written protocols Angulo y González in his experimental report gives the percentages of fetuses showing each movement at each age For these detailed conclusions the reader is advised to consult the original papers (1929a, 1930b, 1932a, 1939) This same author, after using the drug *curare*, which alters the physiological relationship of motor nerves and muscles, was able to stimulate muscles directly in young fetuses This indicates that the first responses of the rat fetus may be purely myogenic

It is interesting to note that both Swenson and Angulo y González independently first observed movement in the rat fetus in the three hundred and seventy-eighth hour after insemination Angulo y González' general description of the developmental process, particularly so far as the process of "individuation" of behavior is concerned, may best be given in his own words

During the early stages of development the appendages move only with the trunk Thus, upon stimulation of the snout the reaction more frequently obtained is a total mass reaction which involves the trunk and appendages This total mass reaction we called a total pattern This total-pattern reaction consists of a primary or basic movement, lateral flexion of the trunk, and a series of secondary movements Similarly, there develops later a total pattern consisting of a basic movement of head extension and a series of secondary movements The basic movements, during the early period of behavioral development, assert then sovereignty upon the secondary movements During the later period of the development of fetal behavior, we find a number of specific reflexes showing what at first seems to be a breaking up of the total patterns into individual and specific reflexes But close study has convinced me that the process by means of which the individuation and specificity of certain reflexes is attained is not a disintegration or breaking up of the established pattern, but, rather, is due to an inhibitory action by means of which the primary or basic movements are in a large measure arrested In other words, the total-pattern reaction is never abolished completely, nor is the dominance of the primary over the secondary movements lost (1932a)

This same investigator (1933a) has suggested that there are three phases in the development of somatic activity in albino rat fetuses (1) a myogenic phase in which behavior can be elicited only by direct muscle stimulation, (2) a neuromotor stage in which internal stimuli acting upon the nervous system initiate behavior, (3) a sensory-motor phase in which true reflex action begins

Angulo y González (1934a) has also shown that the dissolution of the behavioral systems of the fetal rat is in inverse order to its evolution, which is in general cephalocaudal and proximodistal The relationship of this observation to Hughlings Jackson's generalizations (1884) should be noted Angulo y González (1934b, 1939, 1940) has studied in detail the change in neural mechanisms which are correlated with behavioral development

Besides these studies of the whole develop-

mental sequence in the rat there have been a number of investigations devoted to certain aspects of the growth of the activity of the response mechanism in the rat. Lane (1917) has studied the development of the correlation between structure and function of the special senses in the white rat. His method of preparing fetal material consisted of killing the pregnant mother and studying the excised fetuses in a warm chamber. This method is open to the limitations pointed out in the evaluation of Avery's work given above. During the observation period the fetus was bathed in a warm physiological salt solution.

Lane's (1917) observations on the development of the senses in the white rat may be summarized as follows:

Touch. He found no evidence of this sense in $7\frac{1}{2}$ -mm embryos, which are generally agreed to be immobile. Neurologically, at this stage he found both sensory and motor fibers developed. The sensory fibers, however, had not as yet reached the periphery. In 16-mm embryos, that is, in organisms approximately 17 gestation days old, the tactual sense is reported as present on the flanks and snout, as evidenced by motor response to needle pricks. Lane reports no response to stimulation with a sable brush at this time. This is contrary to the findings of all subsequent investigators and is probably a function of the special condition of the embryos used. In 23- to 28-mm embryos, that is, embryos approximately 19 to 20 gestation days old, he reports response to stimulation with a fine sable brush as well as with a needle prick. The snout region is most sensitive, although stimulation about the shoulder, upper arm, hip, rump, and thighs also evokes motor responses. He reports that there is a noticeable increase in the number of vibrissae as well as a greater complexity in the neural fiber basket of the vibrissae follicle. In very late fetuses and newborn rats a still better development of the tactual sense is found, responses being elicited by stimulation of any point on the entire body, including the tail. Pain as the result of needle stimulation is at this period shown by squeaks. The fibrillae baskets in the vibrissae follicles are now elongated cylinders, from the base of which neural fibrils in comparatively large bundles are seen to emerge, distad to the base of the

follicle itself. In later stages there is no particular advance noted in tactual sensitivity, although the snout region continues to be superior to the rest of the surface in sensitivity.

Equilibrium. In regard to this sense, this investigator found in $7\frac{1}{2}$ -mm embryos that stimulation leads to no behavioral trace whatsoever. Histologically, he reports the semicircular canals to be as yet undeveloped. In the 16-mm embryo Lane again found no experimental evidence of the sense of equilibrium, although the semicircular canals are now well developed. In 23- to 28-mm embryos, Lane still finds no experimental evidence of a sense of equilibrium. Histologically, the differentiation of the cells of the cristae is at this time further advanced than in the previous stage, although the sensory and supporting elements are not yet distinguishable. Slight indications of central connection with the cerebrum are noted. In a 35-mm fetus the sense of equilibrium was first observed, as seen in the righting responses of the organism when in contact with a surface. Structurally, the semicircular canals are now virtually complete. On the first day after birth, however, the righting responses were better developed, as were the histological and neural connections seen in the semicircular canals. In later stages there was manifested a greater perfection of the sense of equilibrium accompanying an increasing power of coordinated movement. Lane makes no reference to the part possibly played by neck proprioceptors or by other receptor fields in determining these righting responses, nor is any reference made to the analysis of postural reactions suggested by the school of Magnus, which will be referred to later.

Smell. Lane reports no satisfactory method of smell stimulation in rat embryos from $7\frac{1}{2}$ to 28 mm in length. Histologically, he says "During these stages the olfactory apparatus is being gradually laid down, both as regards its sensory and peripheral portions. The histological differentiation of the olfactory epithelium has not advanced sufficiently far to enable the sensory cells proper to be identified." Using a brush placed in an odoriferous substance, Lane obtained no certain response to olfactory stimuli in 35-mm fetuses. Histological development, however, is noted as

continuing Small's work (1899) on smell in the newborn rat is quoted, and the statement is made by Lane that "there is on the whole a gradual perfecting of the olfactory sense from day to day." No experimental proof is given of this statement, and it is hard to understand its basis in view of the difficulty reported by Liggett (1928) in dealing with this sense in the white rat.

Taste In this sense, Lane reports that the 35-mm fetuses were able to swallow, but neither in these nor in those of any preceding stage were any true evidences of a sense of taste discovered. At no time previous to birth could taste buds or other fully differentiated organs of taste be demonstrated. On the first day after birth, however, he notes that sugar solutions were received with less objection than salt or acid solutions. Lane again makes a generalized statement that in postnatal life this sense is gradually perfected, although no experimental evidence is given to support the view.

Hearing Here Lane reports that "absolutely no response to sound was noted before the twelfth day after birth," and that "from that day to the sixteenth or seventeenth day there is a gradual increase in the ability to perceive sound." No evidence is given for this conclusion in the monograph, however, save that change is inferred from structure. In his conclusions he says:

Previous to the twelfth day the portions of the ear concerned with the perception of sound have been undergoing a gradual development, but have not yet reached that degree of differentiation of the organ of Corti necessary for the perception of sound. By the twelfth or thirteenth day the organ of Corti is apparently differentiated for at least part of its extent, though the lumen of the external auditory meatus is not fully opened. The next few days witness the completion of the differentiation of the apparatus of hearing.

For a study of the early growth of the inner ear of the rat, see Wada (1923).

No better example of cross-species comparison can be given than a consideration of the late development of hearing in the rat and fetal hearing in the guinea pig as described above. The prenatal development of

this sense in the guinea pig and the very similar postnatal development in the rat illustrate how important timing is in developmental processes which are almost certainly in a basic way genetically determined.

Vision As far as this sense is concerned, the report of Lane is "Absolutely no response to light was obtained before the opening of the eyes on the sixteenth or seventeenth postnatal day." This was determined by the use of an electric flashlight. The objection may be raised, on the basis of a good deal of other experimental work, that this stimulus was possibly not strong enough to bring about response. No record is given of the pupillary response which might have been obtained had the eyelids been opened by operation. Histological evidence, however, is given to suggest that there is a neural and receptor development paralleling the reported functional development.

From the report just given of Lane's work, as well as from the incidental observations in the work of Swenson and Angulo y González, it becomes obvious that, of all the sensory fields in the white rat, that of skin sensitivity is apparently earliest and most completely developed during prenatal life. The development of this sense in the fetal rat was quite extensively investigated by Raney, working with the writer (Raney and Carmichael, 1934). In this work the pregnant female was deeply anesthetized and the spinal cord completely transected between the sixth and seventh cervical vertebrae. The result of this operation was to provide an effectively immobilized and, so far as the field of the operation is concerned, a completely desensitized adult organism in which, however, circulation and respiration continue in a virtually normal condition. After a period of $1\frac{1}{2}$ to 2 hours, the fetuses were shelled out, with placental circulation maintained, into physiological salt solution held at 37.5°C by thermostatic control. Raney and Carmichael's work was conducted not only in an effort to study the effect of change of skin sensitivity at various fetal developmental ages, but also to consider the origin of what may be called "local sign," at least insofar as such local sign may be demonstrated in the progress of localizing movements of the limbs of the fetus resulting from punctiform stimulation.

Klemm (1914), in his history of space perception, referred to the development of the view that space is perceived in relation to body movement. James (1890, Vol II) also considered the factors leading to this view, and Peterson's experimental work (1926) on local signs as orientation tendencies again emphasized this conception. Raney and Carmichael's work shows that with increasing gestation age the fetus first becomes sensitive to aërial stimulation, as, for example, to stimulation with a camel's-hair brush approximately 5 mm in diameter. Response to punctiform stimulation by a single light hair is observed to begin some time later. The first appearance of sensitivity is in the head region and is observed to pass gradually caudad (that is, toward the tail). The first responses to stimulation are slight movements of the trunk occurring during the sixteenth day, as noted by previous investigators. As development continues, stimulation at any sensitive point may elicit much more complicated behavior, often involving neck, trunk, forelimb, hindlimb, and other muscle movements. The peculiar sensitivity to tactual stimulation of the region from which the vibrissae issue is noted throughout this developmental sequence. The early function of this tactual organ, as it may be called, is particularly interesting in reference to the full innervation of this area as shown by Lane and in the behavioral observations on the function of the vibrissae in young rats by Small (1899), and especially in the special study of this receptor field by Vincent (1912).

Raney and Carmichael (1934) have found, however, where the mechanical possibility of movement is present, that is, where the limb may touch the surface, that the responses may gradually become more and more precisely related to the point of stimulation. Thus at an early gestation age stimulation of the region of the vibrissae may lead to slight trunk movements. Later such stimulation may lead to the movement of many muscle groups of the fetus, including the limbs. At a still later time, the principal response may be merely the forepaw moved ever so slightly toward the point stimulated. If the point touched is on the body wall, the movement may be toward that point. If it is on the nose, it may be toward that point. It

must be noted, however, that, even at the best time for such differentiated response in late gestation periods, the stimulation of any point may also bring out very general activity. It is possible that such generalized response is due to interruption of some "spontaneous" movement, or that it is related to the strength of stimulation. The frequency of stimulation or the immediate past activity of the organism may also be important in inducing such activity. The significance of intensity of stimulation in this connection in the guinea pig fetus has been explained. This is not the place for a full consideration of the theoretical implications of Raney and Carmichael's study as it bears on space perception, but the results suggest a certain reformulation of one form of a modified genetic theory of the perception of extension as considered by Boring (1929).

To return now to experimental fetal studies, Lincoln (1932), also working in collaboration with Carmichael, was able to show in the rat fetus something of the elaborate sensory and behavioral sequences which are antecedent to the sucking reflex as that reflex is seen at birth. The report of this investigation is recorded in library copies of a thesis (See also Carmichael, 1934a). This work is especially interesting in relation to Lane's work on the correlation between structure and function in the nursing reflex of the young rat and guinea pig. In Lane's work (1924) special attention is given to the development of the tongue both as a locus of taste receptors and as a prehensile organ. Further references to the sucking reflex are given below.

Angulo y González (1937) has shown that the sensory system follows the motor system in development. The earliest functional sensory endings develop in the region of the snout as tactile receptors. The receptors in the forelimbs, for example, are later in development than those in the snout. The total arc connections seem to be formed by the growth of collateral fibers which establish functional connections after the sensory and motor systems are complete. The study of fetal behavior and of the functions of the fetal sense organs is important in an understanding of perception, as indicated later.

Windle (1934b) has demonstrated that

all the spinal reflex arcs are present at 11 mm but they are incomplete because sensory collaterals are just beginning to enter the mantle layer of the spinal cord. The main difference between the nervous system of motile and nonmotile fetuses lies in the number and length of these elements. This same investigator (1944) in an excellent synthesizing article has emphasized that a close correlation can be demonstrated between the time of appearance of reflexes and the anatomical completion of the neural mechanism on which these responses depend.

Besides the special studies noted above, there have been a number of other investigations dealing with particular muscle groups or special behavioral characteristics of the white rat fetus. Corey (1931) has studied the causative factors of the initial inspiration of mammalian fetuses, using the white rat as material. In this study it is concluded that the initial respiration of the fetus is normally brought about by a change in the relationship between carbon dioxide and oxygen in the blood in cooperation with the stimulating effect of the diving of the skin. Blincoe (1928a, 1928b) has worked on the development of behavior in the motor system of the forelimb of the rat. He has elaborately studied the anatomy of the limb before the fifteenth day, that is, just before the onset of motility. An effort has also been made to present a correlation between this stage of development in the rat and in man. In the later study he points out that it seems that the aim of the rat shows "the static assembling of many bodily components which await some complementary addition to render them a dynamic whole" (1928b). It is suggested that this addition is to be found in functional innervation. In this connection see also a paper by Barron (1934) on the results of his experiments on the peripheral anastomoses between the forelimb and hindlimb nerves of albino rats.

Also working with the rat fetus, Windle, Minear, Austin, and Orr (1935) have shown that physiological muscular development may be summarized in the course which it takes. In general this development proceeds from the head to the tail region and distad and ventrad from the dorsal part of the trunk. (See also Windle and Baxter, 1935, 1936.)

Bois (1925), Nicholas (1925, 1926, 1929c), Hooker and Nicholas (1927, 1930), Nicholas and Hooker (1928), and others have performed experimental operations on rat fetuses. Following a very elaborate technique, these students have been able to operate on mammalian fetuses without interrupting pregnancy. In the course of this work they have made a number of incidental observations on the development of motility, and Hooker and Nicholas (1930) particularly have pointed out the fact that during intrauterine existence "movements are restricted to a large degree and there is also a greater degree of independence of the individual cord segments than is found in later postnatal stages." These observations are significant, for they were made under conditions more nearly approaching those of normal development than any other studies of the development of mammals.

Straus and Weddell (1940) have shown that the earliest visible contractions of the forelimb muscles of the rat appear during the latter half of the fifteenth or the first half of the sixteenth postinsemination day. The extensor muscles are more readily stimulated than the flexor muscles, and if a nerve trunk can be stimulated the response is greater than if the muscle must be directly stimulated. (See also Straus, 1939.)

Corey (1934) has shown that in the fetal rat the cortex is not extensively involved in the production of fetal movements. Becker, King, Marsh, and Vierck (1964) have studied the respirationlike movements of the fetus of the rat and guinea pig. They question whether or not such movements are normal or seen only in fetuses experimentally deprived of oxygen. (See also Vierck, King, and Feim, 1966.)

A number of studies of special aspects of the development of behavior have been made on the rabbit, a few of these have been referred to earlier. Preyer (1885) made some observations on fetal organisms of this type. Langworthy (1926) has worked on progression in very young rabbits. He points out that in such animals decerebration does not lead to extensor rigidity but to prolonged progression movements. In the more mature newborn guinea pig, however, rigidity follows decerebration. This difference is attributed to the degree of myelination in

the central nervous system. The importance of myelination, or the formation of the myelin sheaths, on neurons is discussed below. Zuntz (1877) also used the rabbit fetus in his work on respiration. Richter (1925) has observed sucking movements in rabbit fetuses about 20 days old. Pankratz (1930, 1931b) has adapted Swenson's technique to the study of the rabbit. Mechanical stimulation of nose, head, and neck led to response of simple lateral flexion of neck and trunk in 15- to 16-day rabbit fetuses. In a 17-day fetus there was a marked ventrolateral flexion of head and upper trunk, with some movement of the forelimbs. In 20-day-old fetuses, opening and closing of the mouth, active movements of the forelimbs, flexion of the hindlimbs, and lateral flexion of the whole trunk were observed. As the gestation period advanced the movements became more complex.

Thyroid may be necessary for normal development of the mammalian brain *in utero*. In a study using 160 rabbits, the clearest effects on the weight of the body and brain were seen after birth but thyroid treatment had some influence during fetal life (Cuaion, Gamble, Myant, and Osorio, 1963).

The cat has proved itself to be an eminently suitable animal for the laboratory study of the development of fetal behavior. Its neuromuscular system is quite highly organized. Its gestation age of over 60 days allows for the development of an organism at birth that is relatively mature. Much is also known as a result of past research concerning its structural development (Hill and Tribe, 1924; Latimer, 1931; Latimer and Aikman, 1931), anatomy, and certain of its adult behavioral characteristics, such as the fighting response (Camis, 1930). These factors combine to make the animal peculiarly satisfactory for research upon the development of fetal behavior. The general purposes of this chapter, therefore, demand a rather complete summary of the investigations of fetal behavior in the cat.

Windle and Griffin (1931) reported a study in which a large number of cat fetuses of precisely known or accurately estimated gestation age were experimentally studied. The technique employed by these investigators involved an operation on the brain of the mother cat such that later, without anes-

thesia, it was possible to study the fetal organisms under warm physiological salt solution with fully maintained placental circulation. The methods of studying the fetuses varied more or less according to age. In all, 34 pregnant cats were used, giving 125 living embryos and fetuses for study. Of the litters of the 34 cats thus employed, 19 were of known age since copulation. The ages of the other fetuses were calculated from their body measurements, a procedure that is not in all respects satisfactory.

These investigators reported that no movement was seen in the 23-day stage or on any day previous to that. In later studies, however, it was established that movement does take place on the twenty-third day (Windle and Becker, 1940a). In the 24- and 25-day stage, what the reader may now begin to consider as the characteristic response of young fetuses, namely, the very slightest slow ventral lateral head flexion, was observed in a number of embryos. This was also independently confirmed by Windle (1930a). The earliest limb reflexes are well-localized movements occurring on the side of stimulation at the twenty-fourth day (Windle, 1934a). In the 26- to 27-day stage, movements were in general more complex and of greater amplitude or duration and strength than those noted previously. Generalized trunk undulations, however, still formed the permanent background of activity, but forelimb flexion had also begun. The investigators have pointed out that, at this stage, rotation of head and trunk appears to be coordinated with older components, but that this activity results in movements which strikingly resemble the fighting reflexes seen in later fetal life. At this stage the fetuses seem unresponsive to brush or probe. At 28 days slight flexion of the hindlegs was noticed, and at this time also the first responses to touch, particularly in the head region, were observed. Stimulation of this sort was followed by typical apparently "random" head-trunk-limb undulations. At 30 days the activity recorded was still more complex. Active flexion of the hindlimbs was noted, and at the same time definite, although sluggish, mouth movements appeared. From this time until birth, continued and progressive increase in the specificity of behavior was noted by these observers.

So far as the development of sensory capacity in these animals is concerned, it has already been noted that no external response to stimulation is found in fetuses of less than 26 mm, that is, of approximately 28 gestation days. These investigators hold that there is evidence, however, of exteroceptive and proprioceptive function even in the first animals that show spontaneous movements. "The fact that the unilateral trunk or neck flexions seemed always to be executed toward the observer and away from the surface on which they rested may indicate that the earliest sensation is one of deep pressure" (Windle and Giffin, 1931). So far as behavior at the 26-mm stage is concerned, it is held that the activity noted may be the result of a "primitive type of proprioception." This would explain the spread of motor response, although there is some possibility that the wavelike progression of muscular contraction noted is due to the function of long association pathways in the central nervous system.

The first so-called cutaneous reflexogenous zone, that is, cutaneous area, in which stimulation can be shown to lead to response included the nose areas and in general most of the head. Pronounced response in the fetuses at 28 days followed stimulation of the nose. Gradually, as fetuses of later ages were considered, the area spread caudally to the neck, pectoral region, forelimbs, trunk, hindlimbs, and finally to the tail. Windle and

Giffin point out "It is interesting to note that spontaneous motor activity always involved a part of the body before responses could be elicited either locally or at a distance from the point stimulated." The strength of stimulation was also reported as significant in determining the nature of response. Usually the light touch of a brush was found to be ineffective in specimens less than 60 mm long. In a few fetuses a little longer than this a response was secured when the brush was applied to the nose. It was noticed that a light stimulus which caused no response if once applied was sometimes adequate if repeated several times. This effect of summation of stimuli is noted in many fetal forms under a variety of conditions. Very little difference could be observed between strong innocuous stimulation and stimulation producing observable protoplasmic damage. The authors believe that the primitive type of pressure-touch sensitivity, which they postulate as the characteristic state of the receptor surface of early fetuses, was not replaced by definite touch and pain until relatively late in fetal life. In fetuses of 75 to 80 mm marked differences between the responses to light and to strong stimuli were observed, and pain responses were thought to be definitely present.

In the cat, vestibular function probably appears in prenatal life. No absolute evidence of its presence is found until very shortly before birth. It should be borne in mind in

Fig. 11 Apparatus used in the study of the development of the air-righting reflex in small mammals (From Warkentin and Carmichael, 1939)

Fig 12 Diagrams of movement sequences during falling in a young rabbit at three different ages—10 days, 13 days, 20 days. Not every frame is shown. The frames represented are numbered at the left of each diagram, the numbering for each falling sequence beginning with "Frame 1" as the last frame before the jaws opened. Since the film was photographed at the rate of 64 frames per second, and the exposure per frame was about 2 sigma, the time interval from one frame to the next was roughly 15 sigma. All diagrams are drawn to the same scale, hence the animal is larger at the later ages because of normal gain in size and weight during the days represented. (From Warkentin and Carmichael, 1939.)

all considerations of this sense in fetal life that there are great difficulties in testing it accurately in a squirming fetus. In a later study, however, Windle and Fish (1932) demonstrated by the use of several techniques, including the operative interference with the vestibular apparatus, that the true vestibular righting reflex elicited in animals in contact with a surface probably appears in fetal kittens of 100- to 115-mm crown-rump length, that is, on about the fifty-fourth day of gestation. These same investigators (Fish and Windle, 1932) considered the onset of rotary and postrotary nystagmus in the eyes of newborn cats.

For an important early study of the developing of the "falling reflex," see Muller and Weed (1916). Carmichael (1934b) and later Warkentin and Carmichael (1939) studied the genetic development of the kitten's capacity to right itself when falling through the air. Rabbits were also used in the second study. The apparatus used to release the animals is shown in Fig 11, and a typical sequence as drawn from high-speed moving-picture films is shown in Fig 12. These

studies were correlated with studies on the development of vision in kittens (Warkentin, 1938). They show that there is a genetic relationship between the time sequence of the partial responses making up an righting and the performance of the act. Thus an animal may be able to perform all the behavioral acts needed in air righting before the total pattern in time can be accomplished in the short period allowed by a free fall.

From study of the vestibular sense, Windle and Giffin (1931) turn to a consideration of the development of posture and progression in general. In this study they follow in part the analysis of Hinsey, Ranson, and McNattin (1930). Walking can be shown to require the coordination of several behavioral patterns, including the ability to maintain an erect posture. In this connection the analysis of Magnus (1924), which shows that posture may depend on impulses from the various receptor groups of the nonauditory labyrinth, from the proprioceptors of the muscles and associated structures, and from the exteroceptors including touch and the distance receptors, is distinctly relevant. In view of the facts

it becomes obvious that the maintenance of erect posture may demand quite elaborate stimulation and the establishment of postural tonus by the proper neurological balance between flexor and extensor muscle groups. This complex mechanism makes possible successful opposition to gravity and behavioral acts dependent upon such opposition. For an illuminating evaluation of the effect of gravity on the development of behavior in mammals, the reader should consult a treatment of this subject by Holt (1931). Windle and Griffin (1931) further show that the essential receptor and effector mechanisms necessary for progression involve an added condition, by means of which alternate and rhythmic changes in the limbs are brought about. This last component is necessary if balance is to be changed in such a way that stepping movements may be accomplished.

Windle and Griffin report that these mechanisms, which are essential to locomotion, develop at different times during fetal growth. The onset of the righting reflex has just been reviewed. The first positive evidence of rhythmic movement of the forelimbs involving flexion and extension movements, was seen in a 58- to 60-mm fetus. At this time the hind-leg movements were less rhythmic. Occasionally in a 100-mm fetus complete stepping movements were observed. In this connection the study of Laughton (1924) on the nervous mechanism of progression in mammals should also be consulted. It is further suggested by Windle and his associates that the unilateral rhythmic flexion-extension of the limb as seen in the scratching reflex may have a relationship to the occurrence of the alternate rhythms of locomotion. The first indication of the scratch phenomenon was thought to have been observed at the 75- to 80-mm stage, following ear stimulation. These observations show that the walking movement even as seen in prenatal life involves a complex series of factors which are concerned with virtually the entire receptive field and the entire muscular system of the organism.

Besides this characteristic behavior pattern, these same investigators have also studied the development of the sucking reaction, a response which, like that of locomotion, is characteristic of early mammalian behavior and to which reference has been made. The first head raising and lowering of the jaw were

noted in 27- to 28-mm fetuses. This early prefeeding response was followed in the 45- to 50-mm organisms by tongue reflexes which were so amplified in the 70- to 80-mm organisms as possibly to be characterized as sucking. In the 95- to 103-mm organisms, this response had developed so much farther that it was present in virtually its adult form (Windle and Griffin, 1931; Windle and Minear, 1934). Windle and Minear have also shown that the response to faradic shock given to the snout changes with age. At first the reaction is dominantly away from the stimulus (that is, on the opposite side), later, homolateral responses appear. Windle (1937) and his collaborators (Windle, O'Donnell, and Glasshagle, 1933) have also studied the detailed neurology related to the first forelimb responses. At 14 mm, or about 23 days, true reflexes are elicited. At this time the sensory collaterals of the cord are just complete. Windle emphasizes the fact that these responses are not part of a total mass reaction pattern when they first appear. He had previously (1935) shown that the simplest forms of reflex pathways are laid down in the central nervous system before higher integration systems are functional. (See also Windle, Oll, and Minear, 1934.) This same investigator (Windle, 1939) suggests that calcium and potassium deficiencies may account for certain delays observed in the onset of fetal movements.

Another elaborate study of the development of behavior in the fetal cat was undertaken in 1928 by Coronios, working in collaboration with Carmichael and other investigators (Coronios, 1930, 1931, 1933; Coronios, Schlosberg, and Carmichael, 1932). Unlike Windle and Griffin, Coronios used only fetuses from litters whose insemination age he knew accurately. In Coronios' work the pregnant female was prepared for observation under deep ether anesthesia. While the animal was anesthetized the carotid arteries were ligated, a cannula inserted in the trachea, and a complete midbrain section carefully performed. After this section, the anesthetic was immediately discontinued. The decerebrate adult cat was then allowed to remain quiet for 1½ or 2 hours before the fetuses were exposed for observation by an operative technique. Before the observations began, the cat was placed in a specially de-

vised bath apparatus in which physiological salt solution was maintained thermostatically at $37.5^{\circ} \pm 0.5^{\circ} \text{C}$. Into this blood-warm liquid the fetuses were shelled out one by one. A

summary of the behavior observed at various copulation ages may be found in Fig. 13. In a supplement to this chart Coronios (1933) offers the following conclusions:

Fig. 13 A chart constructed to show the development of behavior in cat fetuses of various gestation ages (From Coronios, 1933)

In the early stages the behavior is diffuse, variable, relatively uncoordinated, and weak. With the increase in gestation age, the reactions become more vigorous, more regular in their appearance, less variable, individualized, and better coordinated. These qualitative changes do not occur abruptly but are continuously progressive modifications in the quality of the observed reactions. Moreover, these qualitative changes do not, as it were, "invade" the total organism at once. Rather they seem to follow a general course in their development, beginning at the head region and progressing toward the tail.

It is interesting again to note in this description of the development of behavior in a highly organized mammalian fetus a marked similarity to the description of the development of behavior noted in *Amblystoma* and virtually all other forms considered above. It must be emphasized, however, that there is danger in making too sweeping generalizations about fetal behavior, but it is impossible to deny that there are certain descriptive terms which accurately characterize the development of behavior in many forms.

As a conclusion to his work, Coronios (1933) makes the following points:

- 1 Before birth there is a rapid, progressive, and continuous development of behavior in the fetuses of the cat.

- 2 The development of behavior progresses from a diffuse, massive, variable, relatively unorganized state to a condition where many of the reactions are more regular in their appearance, less variable, better organized, and relatively individualized.

- 3 In the early stages of prenatal development the behavior appears to be progressing along a cephalocaudal course.

- 4 The development of the sensitivity of the reflexogenous zones passes through a continuous and transitional development from a time when rather vigorous stimulation of any "spot" of the body within a large area serves to elicit variable, diffuse, uncoordinated patterns of behavior to a later time when a weak stimulus becomes adequate, within a much more circumscribed area for precise, well-coordinated, uniform, and less variable patterns of behavior. The direction of such development is cephalocaudal.

- 5 The "primitive" reactions of breathing, righting, locomotion, and feeding are the products of a long and continuously progressive course of prenatal development.

- 6 Behavior development appears first in the gross musculature, and in the fine musculature later.

- 7 Behavior develops in each of the limbs from a proximal to a distal point, that is, the entire limb is first involved in the response and then gradually the more distal joints become, as it were, independent of the total movement.

Each of these generalizations is to be taken as a statement of a typical course of development and not as a specific formula that can be applied to other mammals or man in advance of observation. For example, from the time of Aristotle the anteroposterior course of development has been noted (Needham, 1931). This apparently holds true in the primitive gradients of the organism and in the weight of different organs of its developing structure, as well as in the development of "individualized" behavior. This generalization must, of course, be considered descriptive and not explanatory. For further discussion, see Kingsbury (1924, 1926) and Child (1925).

Besides these two elaborate studies of the development of behavior in the fetal cat, there have been a number of incidental studies calculated to investigate some special problem in fetal behavioral growth. T. G. Brown (1914, 1915) reports an experiment on the development of the mechanism of progression in the fetal cat. He used four fetuses of unknown gestation age, the placental circulation being maintained and the observations made in a warm salt solution. The fetuses were studied both before and after decerebration. On the basis of this work he asserts that blood stimulation is very important in eliciting the rhythmic movements seen before birth. He concludes:

It is possible that the "quickenings" movements which are a symptom of human pregnancy may be due to similar progression movements in man, and if they are thus evoked by some such accidental asphyxia as that conditioned by pressure upon the umbilical cord they may tend, in an indiscrimi-

nate manner it is true, to relieve that pressure (1915)

He also suggests on the basis of other observations a phylogenetic theory of the development of locomotion based on Sherrington's view of motor half-centers in the central nervous system

Langworthy (1929) has also studied the development of behavior in the fetus of the cat. He reported a study on six fetuses near term and a number of kittens of varying ages after natural birth. In these fetuses after decerebration he found behavior that is characteristic of the late cat fetus, although less well-defined hindleg movements were observed than those reported by Brown. The behavior of the fetal and young organisms was then correlated with structural studies of the nervous system. He reported in summary of this work

Bilateral movements of the extremities begin to coordinate when the ventral commissural fibers of the cord receive their myelin sheath. The animals turn the body at a time when myelinated vestibular fibers reach the spinal cord. The hindleg movements become better coordinated when myelination becomes marked in the lumbar portion of the cord.

Kinjevic and Silver (1966) have carried out a histochemical study of the developing forebrain of the cat embryo. They believe that acetylcholinesterase-containing elements have a purely telencephalic origin.

Tilney has prepared a chart showing the stream of behavior reaction in the cat similar to the chart concerning the development of behavior in the guinea pig cited above (Woodworth, 1929). In this chart many behavioral acts are shown as appearing in postnatal life which the studies given above show in prenatal life. This is true of "primitive escape," "snatching," and, indeed, virtually all the reactions shown in the chart. The "sudden emergence" of some of these behavior patterns noted below the chart, as in most "saltatory maturation," may seem therefore to involve the reactivation under different environmental conditions of behavior which has had a prenatal developmental history. Similar facts of human fetal devel-

opment are significant in interpreting the conclusions of Gesell (1929b) and Shirley (1931a, 1931b) concerning human behavioral maturation. Windle and Orr (1934b) have shown that when the fetus is dying there is likely to be a vermiform contraction. These general reactions may appear after the heart has ceased to beat.

A number of special studies have been made on other mammals. Erasmus Darwin (1796) quotes an account from Galen of the fetal development of the goat. The fetus, after removal, got to its feet and walked, shook itself, scratched, smelled of objects, and then drank milk. Huggett (1927, 1930) has used this same ungulate in elaborate studies of the onset of breathing reflexes in the fetus, which will be considered below. He used animals 1 or 2 months before full term. The size of the animal made it convenient for operative purposes, but some difficulties which experimenters with small animals are spared may be noted, since a "domestic bath" had to be used to hold the saline solution into which the fetus was delivered (1927).

Scharpenberg and Windle (1938) have now shown that, in the sheep, myogenic responses precede neurogenic ones. Some sensory collateral fibers have grown out from the dorsal funiculus and have reached the internuncial neurones of the cord at the time the first true reflex arcs are established. The most elaborate studies of the fetus of the sheep, however, have been made by Barcroft and Barion (1939). These investigators outline the results of an elaborate series of studies upon this large fetus. In this animal the first spontaneous movements appear on the thirty-fifth day after insemination. These responses involve forelimb, neck, and trunk movements. By the thirty-eighth day the observed movements are more "definite" and the movements are larger and more numerous. Such spontaneous movements are quite transient. Even in a 40-day fetus they may last only 5 minutes after delivery. Maintained posture following movement is seen by the forty-second day. In their study of responses these investigators stimulated by various means the fields related to some of the important peripheral nerves of the body. As a conclusion of the study of the maxillary nerve, for example, they state that the motor

response to specific stimulation is at first confined to a few muscles, then more muscles become involved, but at length only those are activated which respond in the adult sheep. Again, in regard to the sensory nerves distributed to the trunk and limbs they conclude that local muscular reactions are first evoked, but with increasing development more and more muscles may be brought into play.

Barcroft and Barron (1936) have also studied the genesis of respiratory movements in the fetus of the sheep. Barcroft, Barron, and Windle (1936) have shown in the same large embryo localized responses to mechanical and electrical stimulation. These writers conclude that behavior may be considered to have its genesis in localized patterns of response. This conclusion is qualified, however, in a later paper by Barcroft and Barron (1937a), in which a neurological distinction is drawn between reflexes and local contractions, for example, of the neck. These same investigators in another paper (1937b) give an excellent description of the movements of the fetal sheep in midfetal life. Barcroft himself gives a more general description of this work in a paper entitled "The Mammal before and after Birth" (1935, see also 1946).

Barcroft's summary of much of this work appears in his excellent volume of Terry Lectures entitled *The Brain and Its Environment* (1938). In this volume brain activity in relation to its internal environment in fetal and neonatal life is brilliantly described. In all of Barcroft's work the importance of the changing internal environment of the fetus subjected to experimental study is emphasized. For a comprehensive evaluation of these problems see Barron (1950) and Windle (1950).

Comline, Silver, and Silver (1965) have studied the factors responsible for the stimulation of the adrenal medulla during asphyxia in lambs at 115 and 140 gestational days. Edelberg, Kolmodin, and Myerson (1965) in experiments on 50 unanesthetized fetal sheep from 30 to 150 gestation days of age have shown that the electrical steady potential in the fetal sheep brain can be recorded at 30 days and that there is a slight increase in steady potential values during all of the rest of pregnancy.

The dynamics of circulation in the fetal

lamb and its changes in the lamb after birth have been studied by Assali et al. (1965).

Bolk (1926) has made a comparative morphological study of fetuses of the gorilla, chimpanzee, and man in relation to a theory of development. Tinklepaugh, Hartman, and Squier (1930) have studied fetal heart rate in the monkey. Hines and Straus (1934) have studied the motor cortex of fetal and infant rhesus monkeys. The gestation period of the macaques used was taken as 168 days. Fetuses 85 days old showed good contralateral responses of shoulder and head on cortical stimulation. The fingers gained cortical representation during the first week after birth, as did also the facial areas and lower extremities. It seems that the muscles innervated by the dorsal strata of the limb plexus (extensor system) are the first muscles of the extremities to gain representation in the motor cortex.

Incidental observations on other animal fetuses are given by J. F. Craig (1930) in his revision of Fleming's *Veterinary Obstetrics*. Needham (1931) gives tables of the gestation times of scores of animals which are valuable for comparative purposes. For an even more complete table, see Altman and Dittmer (1962).

THE EFFECT OF DRUGS ON FETAL DEVELOPMENT

Preyer (1882, 1885, 1893), as already noted at several points, was a true pioneer in the scientific study of the behavior of the fetus. In his 1885 book he pointed out that the drug curare could inhibit behavior by paralyzing the newborn animals but that immature fetuses were resistant to doses that were large enough to paralyze an adult. In conducting these experiments, he made the important discovery that transmission of this drug through the placenta to the mother from the fetus could take place as maternal paralysis was observed to follow fetal injections.

Ruckert (1930) much later showed that acetylcholine acted on certain guinea pig fetuses and caused them to contract. This pattern of response persisted for a time in neonatal life.

In general, as already noted, it can be said that recent work has shown that the placenta

is not as much of a barrier to drugs as had once been thought. Drugs with molecular weights of less than 1000 can apparently cross the barrier (Eastman, 1956).

Factors that lead to the development of malformation in fetal life are called *teratogenic*. The fact that malformation could be caused by drugs was not widely understood until the tragedy of the malformations that resulted from the administration of thalidomide. Thalidomide was first synthesized in 1953. When pharmacologically tested, for example, by Someis (1962), it appeared to be nontoxic. It was considered to be a good so-called hypnotic drug with favorable sedative effects. It was described as a new nonbarbiturate, sleep-inducing drug (Lasagna, 1960).

In December, 1959, a report of malformation (*Phocomelia*) related to thalidomide was published (Weidenbach, 1959). Soon other similar reports were made (Collins, 1964). In 1962 Lenz reported on 52 malformed infants whose mothers had taken thalidomide during the early stages of pregnancy. Many later reports confirmed this finding. The major defect produced in the fetus by the drug is a malformation of the limbs. The long bones such as the radius, femur, and tibia do not develop in a normal way when the drug acts on a fetus. Fingers are often absent or fused. There are internal organic abnormalities as well (Lenz, 1962).

From an embryological point of view, it seems that the damage results mostly between the third and eighth postinsemination weeks. This has been attributed by Pless (1962) to interference in development in the critical or determinant time for the active growth of mesodermal structures.

Experimental work has demonstrated that thalidomide apparently does not affect all mammals equally but some species are vigorously affected by it. When thalidomide was given to pregnant mice, many litters were found to contain embryos with congenital abnormalities (DiPaolo, 1963). In an experiment in which control animals were studied as well as those receiving thalidomide, results show that no malformations were found in the control animals but 69% of the fetuses of animals receiving the drug showed malformations (King and Kendrick, 1962). In rhesus monkeys, thalidomide sometimes seems to kill the embryo, probably prior to

implantation. Thalidomide produces abnormalities in rabbits similar in some respects to those in human beings and hence rabbits have been much used in studies of the effect of this drug on fetuses (Taussig, 1962a, 1962b).

Comprehensive bibliographies listing hundreds of papers on the effect of thalidomide have been brought together (Food and Drug Administration, 1963). The whole problem of drug dangers to the fetus from maternal medication has been well summarized by Arena (1964). Baker (1960) has prepared an admirable bibliography of 354 references and summaries of the effects of drugs on the fetus. He concludes by pointing out that at the present time more children die from congenital malformations than from certain contagious diseases which were dangerous before the modern era of chemotherapy. His paper discusses the effects of powerful analgesics, mild analgesics, sedatives, tranquilizers, anesthetics, carbon monoxide, curare and related drugs, anticoagulants, antibiotics, antithyroid drugs, carcinogenic drugs, lead, and nicotine. The effect of cigarette smoking on premature birth has been studied by Simpson (1957). One of the first or pioneer studies on chromosomal damage in human leukocytes induced by LSD has been investigated by Cohen, Marmello, and Back (1967).

Radiation damage to the fetus has also been extensively studied (Yamazaki, Wright, and Wright, 1954; Yamazaki, 1966; Miller, 1956; Furchtgott, 1964; Rugh, 1958). The effect of high altitude on pregnancy has been studied. Some striking effects are found but much further work is needed (see Montague, 1964).

The very large body of literature on morphological effects of drugs on mammalian fetuses cannot be fully reported here. It is important, however, to note that marked changes in the structure of the fetus produce marked changes in behavior. It is clear, therefore, that any generalization about the fact that embryonic development is a result of the working of the genetic code alone must be qualified by a full consideration of the effect of drugs and other agents on the embryological development of the fetus after conception. Woollam (1962) has indeed pointed out that the thalidomide disaster may

be considered as an experiment in mammalian teratology and, it may be added, in the development of mammalian behavior. Physical growth and the growth of behavior involves a long series of what are called in this chapter emergent developmental changes. It is hard or impossible in considering this complex development, as seen in some obvious organic defect or in some atypical form of behavior, to determine a single explanation of how the defect arose. Every "normal" development is subject to unpredictable variations. Distinctions between genetic and environmental effects in fetal development are thus very hard to establish. There is evidence that prenatal and prenatating stress may affect adult behavior (Joffe, 1965). As Weiss (1955a) has noted, selective damage to a particular organ by an environmental factor can be referred to differential susceptibilities of different parts of the body. Thus environmental damage, in one respect, may be said to go back to the genes of the organism.

It is, of course, well known that malformed fetuses are often aborted before reaching full term, but the birth of many malformed fetuses (or "monsters," as they are sometimes called) shows that this is not an invariable rule.

In recent years a large literature has developed concerning the effect of rubella (German measles) and many other maternal diseases on the fetus (Mintz, 1958). Maternal influenza has been studied by Coffey and Jessop (1959). In almost all such cases, the structural malformation and especially the atypical brain development that is observed can be seen to lead to the growth of behavior patterns that are not the normal ones of the species. Dagg (1966) has prepared an admirable summary of the whole subject. He gives emphasis to abnormalities found in the mouse fetus but his work has implications for other mammals and especially for the importance of the critical periods in fetal life when teratogenic agents are most apt to produce abnormalities.

It is important in considering abnormal fetal development to differentiate anomalies caused by teratogenic factors from those resulting from mutant genes and linkages. The latter topic has been fully reviewed by M. C. Green (1966, see also bibliography of this topic in E. L. Green, 1966). M. C. Green has

also well summarized present knowledge of how the genes act in normal as well as abnormal development. She points out that in seeking answers to the general questions of how genes (or the genetic code) control development, it is important to remember that in multicellular organisms many kinds of cells are formed. It is clear that although each cell type contains the full pattern of genes that are present in the zygote, only *certain genes are active* in each different kind of cell and then only at specific times. In other words, multicellular development depends on the fact that some genes are called into action at particular times and promote changes that may then call other genes into action or repress the activity of other genes that have been previously active. This involved mechanism is of the greatest significance for the student of behavior. As the relationships of these involved factors become better known, it will almost certainly become clear that some specific changes of behavior that are seen in individuals, even in adult life, may have a basis in genes. For example, some of the changes of senescence almost certainly have their basis in mechanisms such as those just described.

GENERAL ASPECTS OF HUMAN FETAL DEVELOPMENT

Prescientific Study

From one point of view at any rate, all that has gone before in this chapter has been intended to prepare the reader for the consideration of the prenatal development of behavior in human beings. Behavioral development before birth has long been a subject of notice in the human race, but only comparatively recently has it been studied in a systematic and scientific manner.

That the fetus moves before birth is knowledge as old as mankind. Certainly there are references to this phenomenon in the folklore of primitive peoples (Ploss and Bartels, 1927). It is interesting to notice also, so far as the anthropomorphic theory of primitive deities is concerned, that the process of making gods in the image of man even included speculations about god embryos. For a consideration of this topic, see Briffault's work *The Mothers* (1927) and Witkowski (1887). There are references to

prenatal development of behavior in Biblical literature and in ancient Indian and Chinese writings. The Egyptians early began to consider this matter, as is shown in a hymn to the sun god attributed to Amenophis IV (about 1400 B.C.)

Creator of the germ in woman,
Maker of seed in man,
Giving life to the son in the body of his
mother,
Soothing him that he may not weep,
Nurse (even) in the womb
Giver of breath to animate everyone that he
maketh
When he cometh forth from the womb on
the day of his birth

(Needham, 1931¹)

Aristotle taught that the vegetative or nutritive soul existed in the unfertilized material of the embryo (Needham, 1931)²

One of the problems that grow out of the view that the fetus early comes to have an independent existence is the value placed upon human fetal life. This problem of evaluation is essentially ethical rather than scientific. As such, it continues even at the present time to be significant. It is not, however, a topic within the scope of this chapter. Among the numerous treatments of this topic, the monograph by Goeckel (1911) dealing with the changes that have taken place in the evaluation of the life of the unborn human fetus is important. In this monograph the author reviews primitive opinion and the statements of Roman and old Germanic law in regard to the fetus. He presents an excellent bibliography of Roman Catholic theological pronouncements and of civil legal opinions on the value of the life of the fetus. The legal aspect of prenatal life is also given special consideration in a paper by Morache (1904). As already noticed, the earlier history of the evaluation of fetal life is fully considered in Witkowski's detailed *Histoire des accouchements chez tous les peuples* (1887). Much of this work, however, seems to be based upon Cangiamila's *Embryologia Sacra* of 1775, which the writer has not seen.

Modern thinking about the value of the fetus is reviewed in such papers as those of Hughes (1905), Arendt (1910), and Glenn (1911), which treat various aspects of the ethics of dealing with the life of the

unborn child. Present civil and religious discussions of birth control and so-called legal abortions show how current are ethical and legal problems in this field.

From early times people have believed that the mother's thoughts and experiences directly influence the fetus. For many years, however, this view of prenatal influence has existed in the popular rather than in the scientific tradition. That "thought transference" or some mysterious nervous relationship exists between mother and fetus is not generally held today by scientific investigators. Save in the chemical interchange between the two blood streams or in mechanical or infectious transmissions, biology and psychology offer no basis for this view. Compayé (1896) gives a brief history of this superstition. He describes the now amusing assertions of Malebranche in regard to the complete intercerebral sharing of all mental processes between fetus and mother and then carries the subject on to the speculations current in nonscientific writings at the end of the nineteenth century. Compayé does not, however, refer to the remarkable assertions of the philosopher Hegel (1894) concerning psychological embryology, in which mother and fetus are said to be in undivided "psychic unity." This magic relationship is held to be of the nature of animal magnetism, by which the character and talent of the mother are communicated to the child.

That superstitious views of prenatal influence are still discussed may be discovered by reading articles by Coughlin (1905), Walton (1910), Christenbery (1910-1911), Tompkins (1911-1912), Barham (1915-1916), and R. L. Brown (1918). An example of such an observation is the following case described by Morrison (1920). A mother of five healthy children had two teeth removed during pregnancy. She feared that the child

¹For much of the historical material given in various parts of this chapter, the writer is indebted for actual references and for many interpretations to Needham's illuminating history of embryology (1931). For a study of the ideas of primitive peoples concerning generation as they have evolved into modern scientific understanding, the reader is urged to consult Meyer's *The Rise of Embryology* (1939).

²A more detailed history of prescientific studies of fetal behavior is given in the previous edition of this chapter. See second edition (1954) of Carmichael's *Manual of Child Psychology*.

would have a harelip. She became obsessed with the idea. The child was born with a harelip. It proved difficult to convince the mother that maternal impressions were not an accepted scientific cause. In this case just given, one is apparently dealing with an unusual coincidence which seems very like a causal connection to those who participate in it emotionally. To the parent such a conclusion may thus be psychologically if not scientifically pardoned. Until new evidence is presented, however, such cases cannot be considered as having scientific significance. We may still say with some assurance that "prenatal influence" in the sense discussed is a superstition.

Sontag (1966) has summarized the literature showing that pregnant rats and other mammals produce offspring that are affected

by adult environmental conditions. Pregnant rats that are fondled produce less "neurotic" offspring. It is also asserted that severe maternal emotions cause a change in the activity level of the human fetus. In eight cases in which maternal emotion caused increases in fetal activity level the offspring later showed no congenital defects but some were hyperactive, irritable, or had frequent stools.

Scientific Study

We must now turn back in our consideration to the scientific study of the fetus in order to consider what is known about the actual behavioral development of the unborn child. For the purpose of understanding this prenatal development of human behavior, some general idea of morphological development provides a useful baseline upon which

Fig 14 The human embryo of His¹Normentafel as given by Keibel and Elze. The letters designating each fetus, its size in millimeters, and its estimated age in days are: a, 2.1, 12-15; b, 2.12, 12-15; c, 2.15, 12-15; d, 2.2, 12-15; e, 2.6, 18-21; f, 4.2, 18-21; g, 4.0, 23; h, 5.5, 24-25; i, 7.5, 27-30; k, 10.0, 27-30; l, 9.1, 27-30; m, 9.1, 27-30; n, 10.5, 31-34; o, 11.0, 31-34; p, 11.5, 31-34; q, 12.5, 31-34; r, 13.7, 31-34; s, 13.8, about 35; t, 13.6, about 35; u, 14.5, about 37-38; v, 15.5, about 39-40; m, 16.0, about 42-45; x, 17.5, 47-51; y, 18.5, 52-54; z, 23.00, 60. (From Keibel and Elze, 1908.)

to represent the changing continuum of behavior (See Goldstein, 1904, for an important early approach to this subject) Figure 14, taken from Keibel and Elze (1908), shows a selected series of human embryos and fetuses 21 to 23 mm in length. The length of each specimen is given in the legend below the figure.

Many efforts have been made to compile a table from which the ages of fetal human organisms can be estimated on the basis of known physical measurements. Scammon (1927), indeed, estimated that there were 7500 titles on the growth and physical development of the fetus, infant, and child. The construction of satisfactory norms of growth in prenatal life has proved to be a very hard scientific task because of the difficulties that must be overcome in evaluating the material to be measured. In the first place, even if organisms of truly known age were plentifully available, each age norm would necessarily be stated in terms of some statistical average, because of the many factors such as genetic stock, nourishment, and specific pathology which influence fetal size. For a consideration of some of these factors in infrahuman mammals, see the work of Bluhm (1929).

A greater stumbling block than this variability of size at any true age, however, is found in the fact that it is peculiarly difficult in the human individual to place correctly the starting point of development, even though, in the light of the discussion given at the beginning of this chapter, such point be taken as the moment of fusion of the nuclei of the two parent cells. As a matter of fact, this moment can never be absolutely accurately determined, and therefore many different ways of approximating the zero point of development have been used in the history of human embryology. Even now no complete agreement has been reached as to the most desirable procedure in arriving at this calculation. Of these methods the following are probably most important:

1 *Menstruation age* In this scale the age of the fetus is calculated from the first day of the last period of menstruation prior to the onset of pregnancy (Mall, 1918).

2 *Mean menstruation age* This age is similar to the above, except that it is based

on the average calculated from many cases. Thus if 51 days is taken as a mean, there is a possible deviation from 40 to 62 days, so far as the relationship to morphological measurement is concerned (Mall, 1918).

3 *Conception age* The age of the fetus is calculated from the last day of the last menstrual period prior to pregnancy. This is the age used by His and adopted by Minot (1892).

4 *Copulation, or insemination, age* This age, based upon calculation and upon trustworthy cases of known copulation time, is found to be approximately 10 days shorter than the mean menstrual age defined above (Mall, 1918).

5 *Ovulation age* This age is calculated from the time of ovulation. It is at present extremely difficult to determine directly the time of ovulation. Determinations are complicated by many factors, such as the observation that it is difficult to know how long spermatozoa may live after entering the female genital tract, and by many other considerations. A complete and critical study of the time of ovulation and the fertile period of the menstrual cycle is given by Hartman (1936) in a book devoted to a consideration of recent data and theories in this field.

6 *Fertilization, or true, age* This age cannot at present be directly determined, but must be calculated from 1, 2, or 4 above. In general it may be said that the present evidence points to the fact that fertilization occurs in less than 48 hours after copulation (Mall, 1918).

A standard table of age-length equivalents during the prenatal period of development is still further complicated by the fact that the linear measurements of the specimens have been obtained by different methods. The measurements commonly used include the crown-rump length and crown-heel length or standing height. The second of these is really related to the first, that is, it is crown-rump length added to the rump-heel length (Minot, 1903). Besides these two usual measurements, there is the *Nackenlänge* of His, that is, the length measured from a particular point in the caudal bend to a particular point in the neck band of the specimen (His, 1880, 1882, 1885).

Of these measurements the crown-rump

measurement is possibly best for embryological purposes (Minot, 1903), but in most of the work on the development of behavior the crown-heel length has been employed (Minkowski, 1923, 1928a, cf also Scammon and Calkins, 1929)

In a subject so full of possible divergences of opinion, therefore, it is little wonder that many apparently conflicting tables of age length relationships have been produced. Among the tables frequently referred to are those of C. M. Jackson (1909), Freyer (and the other embryologists summarized by him) given in Minot (1892), and the summarizing table from Keith (1913). Instead of giving all these tables and many others to which reference might be made, or of attempting any averaging of the results, it has seemed wise to present Mall's (1910) table, which seems to the writer to be based on excellent evidence. This table, based on Mall's own work and upon the collection of material by Issmer, is given as Table 1. Mall (1918) has reviewed his work subsequent to the publication of this table and finds the table still accurate. It should be noted, however, that particularly so far as the younger stages are concerned there is a possibility of great variability in judging age from such a table as that given. Weight is probably a better index but is seldom given (Minot, 1892). Therefore, in all age determinations given in this chapter, it should be borne in mind that the word "approximate" should really be placed in front of almost any statement of fetal age. Streeter (1920) has prepared a series of growth curves of the human fetus based upon most carefully computed data. In his tables and graphs the relationships of weight, sitting height, head size, foot length, and menstrual age of the human embryo are presented. Hooker (1944) has suggested that length and weight provide a more useful index of behavioral development than does age (Gesell, 1928).

Estimation of gestational age from weight of a fetus is subject to uncertainty. Sex, race, genetic background, nutrition and other factors are important in determining weight. Recent work suggests deriving equations which contain a parameter for estimating the weight of the fetuses at various gestational ages. This equation may be fruitful in comparing weight of fetuses from different popu-

From Keibel and Mall (1910)

lations (Spencer and Coulombe, 1964). The study of the embryology of the brain both in terms of its gross structure and its histology is important in understanding the physical basis of behavior growth. The present state of this subject is well reviewed by Robinson and Tizard (1966). They point

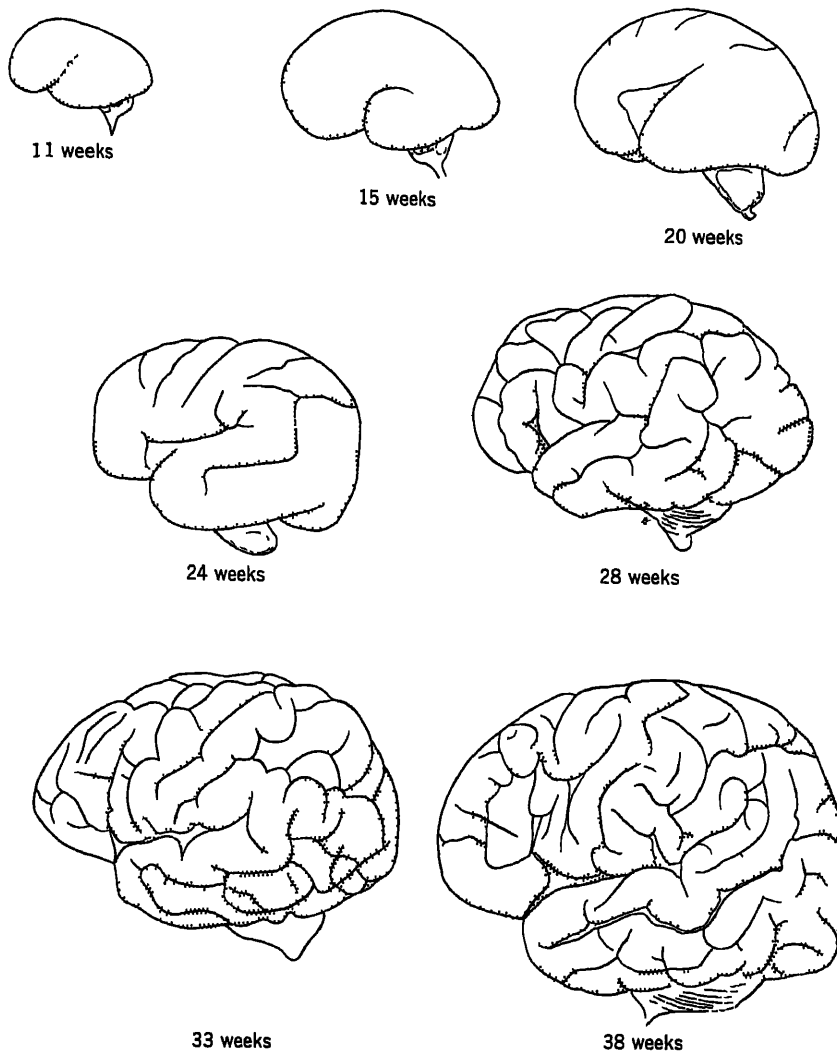

Fig 15 The external appearance of the brain of babies born at different gestational ages After Larroche, 1962)

out that the brain of a full-term infant is $\frac{1}{4}$ the weight of the adult human brain. This can be compared with a proportion of about $\frac{1}{20}$ for other organs. It is also important to note that all neurons are present at $7\frac{1}{2}$ months from conception. The later fourfold growth of the brain is mainly due to the deposit of myelin and the elaboration of dendritic processes and vascular tissue. Figure 15 shows the external appearance of the human brain at various fetal ages. The difficulty of predicting behavior from a study of the brain alone has been emphasized by many writers (Carmichael, 1940a). See also

Borkowski and Beinstine (1955) for the electroencephalography of the fetus.

Arising immediately out of the relationship between growth and age of the fetus is a whole series of studies on the morphological development of the fetus, which of course cannot be reviewed in this chapter. Figure 16 shows graphically the significance of such knowledge for one who thinks of the fetus as a "smaller infant." The literature on general fetal development has several times been summarized, the early work having been brought together in an excellent summary by Pinard (1877). In this summary the work

Fig 16 Changes in body proportions in fetal life BH—body height, ML—midline (From Hess, 1922)

on the morphology, physiology, and pathology of the fetus is treated separately. A bibliography of 870 titles is appended to this treatise. Next to Pinard's summary in importance is Wertheimer's (1904), which brings together the general literature on the fetus to 1904. Probably the most complete summary in English of the anatomical and physiological aspects of fetal development is Feldman's (1920), which, in spite of certain lacunae, should be read by all who are interested in the fetus. Noback and Robertson (1951) have studied the sequence of appearance of ossification centers in the human skeleton during the first 5 prenatal months and have summarized previous work on skeletal development of the human fetus.

As pointed out above, it may almost be said to be necessary, in order to understand the development of behavior, to have some reference line in terms of measurements of anatomical development. It has become a convention by following such a temporal line to divide the prenatal life of the human being into three periods (Feldman, 1920; Williams, 1931). The first period of 1 or sometimes 2 weeks is spoken of as the *germinal* period. From the third to fifth or sixth week is the *embryonic* period. From the sixth week to birth is the *fetal* period. The normal term of pregnancy is usually placed at 280 days (Williams, 1931), although estimates varying between 270 and 284 days have been given by various investigators and summarized by Needham (1931). It must be obvious, however, that such figures are mean-

ingless unless the method of calculating true fertilization time is given. The normal length at birth is ordinarily given as 500 mm in crown-heel, or 320 mm in crown-rump, length. Sometimes, however, premature infants are born and successfully reared who have passed less than 180 days in the mother's body, but 180 or 181 days is usually taken as the average lower limit below which viability cannot be maintained (Hess, 1922). Claims have been made that much younger fetuses have been raised, but as, for example, in the case of Rodman's fetus which was alleged to have been but 4 months old, there is much doubt of the accuracy of the age estimation (Rodman, 1815; Baker, 1825).

At the other end of the scale the terminal point of postmaturity is also open to great difficulty of estimate. In considering this matter, Ballantyne and Browne (1922) hold that no single index such as fetal length, weight, ossification of the skeleton, placental structure, or cord structural condition is sufficient to date the fetus. They state that the best estimate is obtained by combining a knowledge of the last menstrual period, the date of copulation, the date of the onset of morning sickness, the date of the quickening of the fetus, the size of the uterus, the difficulty of delivery, as well as the evidences of postmaturity such as measurements of length, weight, and ossification. Probably 334 days is the longest period legally considered during which a fetus may be thought possibly to have lived in the mother's body and still be delivered alive (Ballantyne and Browne, 1922). Thus, from one point of view at any rate, the human fetal life span that will be dealt with in this chapter must be taken as lasting from fertilization until birth, a time which in the extremest possible cases may vary by as much as 154 days!

That mere age or anatomical development is not enough to determine developmental level is suggested by Arshavsky (1968), who says, "The physiologically immature neonate differs from the physiologically mature by neither length of the gestation period nor birth weight, but by physiological peculiarities suggested by retarded development."

In this chapter most of the references to fetal behavior are made to unborn fetuses. It should be kept in mind, however, that the study of correctly dated premature infants

may throw light upon the later fetal period. In interpreting the sensory ability or response activity of a prematurely born infant, it is not safe to attribute the same abilities to the unborn fetus of the same age. As suggested in the first part of this chapter, the greatest errors in genetic science are made by suggesting that because environmental conditions of one sort produce behavior of a particular kind in one individual, therefore these same abilities must be "implicit" in an organism living under wholly dissimilar conditions. A normal fetus of the same age as a successfully an-breathing premature infant may act in a very different way from the comparison organism. This is true not only because of mechanical differences of bodily make-up, such as the presence or absence of liquid in the ear, but because of the gross differences brought about by the change from placental respiration to pulmonary respiration and from placental nourishment to alimentary canal nourishment. The sheer me-

chanical change from life in a liquid with the specific gravity of the amniotic fluid to life in air is most important. Similarly, the effectiveness of external stimulation is vastly changed in the transition from a relatively constant stimulus world before birth to a continually changing and varied set of physical energies after birth. An excellent brief summary of the development of the fetus week by week is given by Williams (1931). In the present chapter, save for the tables of fetal length and age, and save for the reproduction of the famous Keibel and Elze series of embryos and fetuses given above, no detailed consideration can be given to gross structural change which occurs during prenatal growth.

An interesting graphic representation of prenatal physical development is that in Fig 17, reproduced from Scammon and Calkins and redrawn by Needham (1931), in which the age, height, or weight can, to the limits of accuracy of the original data, be read off

Fig 17 Three-dimensional isometric projection from which height, weight, and age of human embryos may be read off if one is known (From Scammon and Calkins, 1924)

if any one of these measurements is known (See also Streeter, 1920)

In a paper entitled "Physical Fitness in Terms of Physique, Development and Basal Metabolism" Wetzel (1941) presents a critique of a new method of evaluating individual progress from birth to maturity which suggests that there are types of physique which influence all growth tables. A similar observation could undoubtedly be made of fetal life as well. In this connection a study of body build by Sheldon and his collaborators (Sheldon, Stevens, and Tucker, 1940) should be consulted. For a convenient graphic age conversion scale, see McCarthy (1936).

In the paragraphs below a review of the development of behavior in human fetal life without detailed reference to morphology is presented. In this presentation brief consideration will be given to clinical observations made on fetal movements without operation on the mother or the interruption of pregnancy. After this discussion, as accurate and complete a summary as possible will be given of the experimental studies on the development of behavior in operatively exposed human embryos. After these lines of evidence of fetal behavior have been summarized, a review of the knowledge concerning human fetal sensory life will be presented. A knowledge of sensory development will at once lead to a consideration of the theories that have been proposed to account for the development and control of fetal behavior, and an evaluation of all these observations for human psychology will then be presented.

NONOPERATIVE STUDIES OF BEHAVIORAL DEVELOPMENT IN THE HUMAN FETUS

Numerous methods have been used for the scientific study of the development of the human fetus without disturbing its normal course of development. The simplest of these methods involves the direct recording of reports of the mother concerning the movements of the fetus as she experiences such movements. A mother can sometimes perceive the "quickening of the fetus" by the seventeenth week (Feldman, 1920). At times the physician may by the use of the stethoscope hear fetal movements as early as the fourteenth week (Mailhot, 1856, Neu, 1915).

It is customary, however, to say that the first time at which such movements can be detected by the physician is in the fifteenth or sixteenth week (Feldman). Feldman points out that in fetuses of 8 weeks the umbilical cord shows regular spiral twists. Since such twists are not characteristic of animals that carry many young and therefore have little room for the fetus to turn in, it is assumed that the movements of the fetus even at such an early age determine the twisting of the cord. The writer, however, can see no reason why such twisting might not result from passive as well as from active movements.

In later periods of pregnancy, mothers give reports of movement involving part of the body. Sometimes the movements of the extremities or of the trunk alone are noted. Mermann (1887), for example, reports a case of rhythmic movement of the fetal back palpated through the mother's abdominal wall in a fetus of 7 months. Whitehead (1867) gives an extended report of a case of violent convulsion of the fetus while still in the uterus. This convulsive condition occurred during the ninth month of pregnancy. The activity of the fetus caused the mother great pain. By palpation and by direct observation it was found that the fetus was in a state of marked hyperactivity. Both the head and limbs of the fetus were moved so violently as to cause active disturbances of the mother's body wall. The child, born 21 days later, was in all respects healthy and vigorous.

Palpation and various instruments for magnifying or recording various fetal movements observed through the intact body wall of the mother have long been in use. MacKeever (1833) pointed out that the stethoscope was a valuable instrument in this connection. The direct hearing and registering of fetal heart beat also have long been a subject that has attracted the attention of clinicians. Feldman (1920) says that this phenomenon was discovered by a Swiss physician, but its importance was first brought out by de Keigala-dee (1822, 1823). This student concluded that the fetal heart beat could be heard from the eighteenth week of pregnancy on. Mailhot (1856) thought that it could be heard much earlier. Later, among others, DeLee (1927, 1928) and Hyman (1930) made special studies of the fetal heartbeat, includ-

ing such phenomena as irregularities in its rhythm

In 1891 Pestalozza succeeded in taking a cardiograph of the second twin after the first twin had been born (Feldman, 1920). In this he was more successful than Hicks (1880), who by the use of an instrument like a cardiograph obtained certain records which were, however, so badly obscured by the rhythmic activities of the mother that they could scarcely be identified. Krumbhaar and Jenks are reported by Feldman (1920) as having obtained typical electrocardiographic tracings of the fetal heart (See also Sachs, 1922). Maekawa and Toyoshima (1930) have, by the use of amplifiers and a string galvanometer with electrodes placed on the front abdominal wall of the mother, secured excellent electrographic tracings of the fetal heart. After birth the beat of the same heart is also recorded for purposes of comparison.

Stimulated by this work, Carmichael in 1935 attempted, with equivocal results, to record normal fetal heart activity by high-gain amplification. More recently, Mann and Bernstein (1941) and Geiger, Monroe, and Goodyer (1941) have published in this field, and the physiological psychologist D. B. Lindsley (1942) has published a most interesting paper on the heart and brain potentials of human fetuses *in utero*. In this paper a reliable method of recording maternal and fetal electrocardiograms is given. What is even more interesting, however, is the fact that this investigator has also been able to record fetal electroencephalograms. In the latter case, during the seventh and eighth months of human pregnancy electrodes were at times placed on the maternal abdominal wall over the palpated head of the fetus. By suitable amplification and recording, fetal electroencephalograms were secured by this means. The records were typical of those from the precerebral region of the brain in the newborn. In all work upon fetal or neonatal heart rate the effect of asphyxia must be considered (Baicroft, 1938). A fall in heart rate that is nonvagal has been demonstrated in fetal rabbits by tying off the umbilical cord (Bauer, 1938).

A number of recent studies have been made of the electroencephalograms of the fetus showing irregular slow waves with superimposed fast waves (Boikowski and

Bernstine, 1955). Anoxia leads to high-amplitude-low-frequency activity which may end in complete absence of electrical activity (Huhma and Jarvinen, 1963). The electroencephalograms of the fetus during birth is similar to that of the alert neonate (Rosen and Satian, 1965).

Recently, ultrasonic pulse echo techniques have been used in estimating fetal development. Studies show that it is possible within known limits of accuracy to estimate the weight of the fetus by this technique. Animal studies show that there are no toxic effects by the use of this method (Thompson, Holmes, Gottesfeld, and Taylor, 1965).

Among the other early movements of the fetus which are often directly recorded are the so-called *Ahlfeld breathing movements*, or the rhythmic contractions of the fetal thorax felt through the mother's body. These movements should not be confused with uterine contractions occurring after the third month, sometimes called *Ahlfeld's sign*, which incidentally may have something to do with the onset of behavior, if an analogy with the amnion contraction of the chick noted above may be suggested (Kuo, 1932c). In spite of the difficulty of the ancients concerning fetal respiration that involves the intake of no air into the lungs, it has of course long been understood, as Leonardo da Vinci knew, that the fetus does not breathe water (Needham, 1931). The gaseous interchange of the mammalian fetus occurs in the placenta between the bloodstream of the mother and that of the fetus. The general significance of this process and its detailed consideration have been studied by many physiologists. The history of the early advance of knowledge on this matter is summarized by Stalling (1900), and the generally accepted facts about the fetus are brought together by Sarwey (1915) and more recently by Baicroft and Mason (1938) (See also Bylchick, 1921).

The liquid environment, of course, completely precludes true lung breathing, but at least since 1798 movements of the chest and thorax of the fetus similar to breathing movements have been occasionally noticed. Béclard (1815) observed such movements in various mammalian embryos without removing the amniotic sac through which they were observed. Ahlfeld (1890) has developed a view on the nature and significance

of certain irregular but vaguely rhythmic movements of the fetus which seem to be caused by the contraction of the same muscles which will make respiration possible in postnatal life (See also Kouwer, 1919, and Kellogg, 1930) Ahlfeld has made graphic records of these movements, which in typical cases vary from 38 to 76 per minute. C. A. Smith (1946) has presented an admirable summary of the fetal aspects of respiration. He discusses the experimental literature in this field. The point is made that respiratory movements of the fetus of animals studied cannot be considered as automatic, constant, and progressive. His view is rather that here again, as in so many other aspects of fetal behavior, we see the setting off of a response pattern under certain conditions which otherwise, although acquired early, is normally held in abeyance for later use.

If these speculations are in any sense correct, therefore, the so-called first breath of the child may be considered to be just a change in the way in which the same neuromuscular mechanism determines the oxygenation of the blood (Walz, 1922). For an excellent popular statement concerning the onset of breathing, see Henderson (1937).

Barcroft and Karvonen (1948) have studied the effects of carbon dioxide and of cyanide on fetal respiratory movements. They conclude that cutaneous sensory stimulation rather than asphyxia is responsible for the commencement of an breathing.

A number of investigators have severely criticized the Ahlfeld concept of prenatal breathing movements. Walz (1922) attributed these objections to the fact that the initial statement of Ahlfeld's view was unfavorably received by the two leading obstetricians of Germany at the time, and that the weight of authority long kept this phenomenon from being correctly evaluated. It should be noted, however, that Huggett (1930), in an experimental study of fetal respiratory reflexes previously referred to, says "The exact mechanism suggested by Ahlfeld is not in every sense confirmed."

A good many speculations have been made as to the causes involved in the first intake of an breath. As noted above, many students have held that the increase of metabolites, and especially of carbon dioxide tension in

the blood, is one of the essential causes of the first gasp (Corey, 1931). Cohnstein and Zuntz (1884) observed that in a fetal lamb clamping of the umbilical cord led to the first intake of air. Carmichael has noticed this same result in fetal cats, rats, and guinea pigs. Indeed, the procedure of clamping the umbilical cord to study the effect of the blood stimulus on general bodily movements has been part of the experimental technique of several investigators and notably so of Swenson (1926). In his study of the fetal rat, Angulo y González (1933b) reports that in fetuses of 19 postinsemination days in which tactile stimulation of the hindleg aroused no response there was immediate response after ligation of the umbilical cord. The general result of this procedure seems to be an increase in amount and vividness of activity for a time. Pflüger (1877), however, held that some external stimulus, such as cold air, was necessary besides blood change to bring about the first breathing act (cf. Huggett, 1930). Preyer (1885) also suggested a relationship between cutaneous stimulation of some sort and the onset of breathing. Corey (1931) holds that an increase in the metabolites of the blood stream and some external stimulus, such as drying of the skin, seem usually to be antecedent to the initial respiratory gasp. It is suggested by Fender, Neff, and Binger (1946) that *asphyxia neonatorum* may play some part in the development of certain cases of epilepsy in human beings. For a general consideration of this problem see Windle (1950).

Goodlin (1965) has studied the factors associated with breathing in fetal rabbits in an incubator. These studies seem to indicate that external stimuli are not alone responsible for the first breath. It is interesting that these studies show that the smaller fetuses of the litter have the best breathing record.

Snyder and Rosenfeld (1937) have made direct studies of the onset of respiratory movements. They have studied the fetuses of the cat, rabbit, guinea pig, and man. Rhythmic respiratory movements are initiated in all these types in the uterus. Oxygen and carbon dioxide affect fetal breathing movements, a certain level of carbon dioxide, for example, is essential to the maintenance of fetal respiration.

Windle, Monnier, and Steele (1938) and

Abel and Windle (1939) show that there are no respiratory movements in cat fetuses less than 13 mm in length. But in the middle third of the gestation period delicate and rapid rhythms of respiration may begin. Under certain conditions carbon dioxide breathed in by the mother starts such movements. There is no significant increase in blood volume at birth in the pulmonary system. There is a circulation in the lungs during the last part of pregnancy capable of caring for oxygenation when air breathing is established. For a more detailed consideration of the blood gases of the cat fetus, see Steele and Windle (1939), and for a consideration of the physiology and anatomy of the respiratory system in the fetus and newborn infant, see Windle (1941b). See also Potter and Bohlander (1941), Whitehead, Windle, and Becker (1942), and Zettleman (1946).

Besides "breathing movements" there are other movements of the fetus which are indirectly significant in behavior. The movements of the organs of the digestive tract as seen in fetal organisms have been studied by a number of investigators. Yanase (1907a, 1907b) has studied peristaltic intestinal movements in fetal guinea pigs, cats, rabbits, and men. As a result of these studies, he concludes that peristaltic movements may begin long before birth. The status of gastrointestinal activity *in utero* has also been studied, especially in the cat and guinea pig, by Becker, Windle, Barth, and Schulz (1940), Becker (1941), and Becker and Windle (1941). In man such movements are possible in the seventh week. So far as hunger contractions are concerned, Patterson (1914) has shown that hunger contractions are practically continuous in young dogs. As age advances these contractions decrease in magnitude. Carlson and Ginsburg (1915), working on fetal dogs and newborn children, have written "The empty stomach at birth and in the prematurely born exhibits the typical periods of tonus and hunger contractions of the adult, the only difference between infant and adult being the greater frequency and relatively greater vigor of these periods in the young." For other aspects of the function of the stomach before birth, see Sutherland (1921).

Certainly, in view of the large amount of work on the "hunger drive" as a determinant

of activity, part of which is summarized by Warden (1931), the possibility that these stomach and intestinal contractions are stimuli to "random" and "spontaneous" skeletal muscle movement, and indeed to much of the behavior of the premature or full-term infant, cannot be neglected by one who would understand fetal behavior. Such behavior initiated by internal stimulation may well be considered merely the setting into action of inborn neural mechanisms. In this connection, see De Snoo (1937) and Sontag, (1941).

Excretion of urine by the human fetus is well established. Fetal urine is the source of part of the amniotic fluid (Potter, 1961).

The question has often been raised as to whether gross external fetal movements of the various sorts considered above have any part in the rearrangement of the fetus in the uterus in the normal position for delivery at birth. As so often happens when a phenomenon is difficult to explain, it has been alleged that the position of the fetus is governed by instinct (Dubois, 1833). Mechanical and physical explanations have been advanced by Paramore (1909), Bainum (1915), Griffith (1915), McIlroy and Leveikus (1924), and others. Possibly it may be said that no absolutely positive proof has been advanced to show that active fetal movements are essential in determining the normal position of the fetus at the time of delivery. Langieder (1949a, 1949b) has considered the posture of the fetus in relation to fetal reflexes and position at birth.

It seems increasingly clear that fetal attitude or posture, however, is a result of fetal movements in the late fetal period. The normal attitude of moderate flexion of the spine with limbs well flexed and close to the body may be changed by vigorous kicks of the legs or by the umbilical cord becoming wound around the neck and other anomalies (Barnett and Narn, 1965).

In the study of the changes of fetal position before birth, much has been learned by the use of the X-ray. Avery (1928) attempted to study the changes in position of guinea pigs by the use of roentgenograms. This work of Avery's was directly adapted from human clinical procedures used in the study of the fetus. The use of the X-ray in the study of the fetus has given a new clue to the deter-

mination of the fetal age by the study of the ossification of the fetal skeleton, although it is by no means an absolute clue Hess (1918) has brought together much of the literature on this subject and suggests approximate norms of ossification at certain periods (See also Mall, 1906, and Adair, 1918) The study by Rudolph and Ivy (1933) on the rotation of the fetal head shows that uterine contractions and the movement of the fetus both contribute to this change in posture Danforth and Ivy (1938) have shown that uterine activity is in part at any rate a function of calcium Augmentation of uterine activity is brought about by increasing the calcium present, by decreasing the calcium the action is depressed In this connection it is interesting to note that Good (1924) has shown that a patient may have the spinal cord completely severed and still give birth to a baby normally and painlessly

A phenomenon of prenatal and immediately postnatal behavior which has long attracted attention is the first cry of the human organism Kant (1799) found significance in the first sound uttered by the human infant Peyer (1893), indeed, quotes Kant as saying

The outcry that is heard from a child scarcely born has not the tone of lamentation, but of indignation and of aroused wrath, not because anything gives him pain, but because something frets him, presumably because he wants to move, and feels his inability to do it as a fetter that deprives him of his freedom

Both Peyer (1893) and Compayré (1896) have pointed out the futility of such verbal fancies Such speculation, however, is not as yet entirely dead An analytical psychiatrist who is quoted by Blanton (1917) has written of the cry of the human infant at birth "It is an expression of its overwhelming sense of inferiority on thus suddenly being confronted by reality, without ever having had to deal with its problems" By operative technique Minkowski (1922) has found that crying occurs as early as the sixth month in the prematurely delivered fetus In clinical practice many cases of *vagitus uterinus*, or fetal crying, have been reported A typical case is that reported by M. Graham (1919), in which in a difficult delivery, the fetal sac having been

ruptured by operative means to assist delivery, the crying of the still unborn fetus could be distinctly heard Many such cases are reported, but they need not be reviewed here (See also Feldman, 1920)

All cases of fetal crying reported above seem to be the result of appropriately activated muscles, which bring about the expulsion of air in such a way as to cause it to vibrate There seems to be no reason to assume that this phonation has any greater mechanistic significance than many of the other random acts of the child It catches the notice of the observer, however, because from such behavior language develops in later life This function is, of course one of the most important aspects of adult human behavior, and an aspect which will in itself come to be, at least in the subvocal stage of 'verbal thought,' peculiarly important even in strictly introspective psychology

Fetal hiccup has also been reported by a number of observers These cases are summarized by DeLee (1928) See also a study by Norman (1942)

Recently an effort has been made to predict postnatal development from fetal activity Thirty-five women recorded felt movements during the last three months of pregnancy These babies after birth were tested on the Gesell Developmental Schedule at 12, 24, and 36 weeks Total fetal activity correlated significantly with some Gesell scores At 36 weeks, for example, all correlations between fetal activity and motor, language, and "total Gesell scores" were significant (Walters, 1965)

Two types of fetal crying have been reported One is a soft whimper early in labor and the second is loud and gasping and related to fetal asphyxia (Blair, 1965)

This concludes the consideration of human fetal behavior of the sort that can for the most part be studied during the normal course of development In the next pages the study of the development of human fetal behavior in fetuses removed from the uterus before the end of the normal term of gestation will be considered The relationship of criteria of maturity at birth has been considered (See Vincent and Hugon, (1962, and papers in Wynn, 1965)

THE STUDY OF BEHAVIOR IN OPERATIVELY REMOVED HUMAN FETUSES

Most of the living human fetuses to which reference will be made in the next paragraphs were removed while still alive from the mother's body because some disease of the mother rendered the artificial termination of pregnancy medically necessary. Minkowski's technique (1928a) is typical. This investigator and a collaborator removed each fetus that was to be studied by a Caesarean section, usually performing the operation under a local anesthetic. The fetus, placenta, and amnion were removed. The fetus was then placed in a bath of physiological salt solution at normal blood temperature. This meant that such fetuses were cut off from their oxygen supply, and the movements which resulted must be thought of as the movements of increasingly asphyxiated organisms. This is important in the evaluation of the behavior reported, for, as we have pointed out, increased metabolites in the blood at first lead to hyperactivity and then to hypoactivity.

The behavioral development of the human fetus as determined in operatively removed cases will be considered here in one series. This has its disadvantages because in certain reports estimated age is given, in others only measurements are presented, but certainly for an understanding of development it is most important to give estimated age. The writer has attempted to make a summarizing table of human fetal development, but he does not feel that such a table gives a correct impression. One who wishes to see this material expressed as well as possible in tabular form should consult Coghill (1929c).

The development, then, of human fetal behavior as observed by various investigators in relation to estimated postinsemination age or menstrual age may be given as follows:

Fetuses Less than 9 Weeks Old

In very young human fetuses operatively removed from the mother, the first movement observed is of the beating heart. For several centuries there has been a scientific controversy as to whether the heartbeat is to be thought of as primarily determined by direct muscle or by neural stimulation. It now seems that the early embryonic heartbeat must be thought of as essentially an independent mus-

cle contraction (Parker, 1919). Therefore, in most of the work on the development of behavior the beating of the heart is not considered to mark the onset of "true behavioral life." Pflüger (1877) has demonstrated the beginning of heartbeat in the fetus as being in the third week, that is, in a fetus of approximately 4 mm. (See also Strassmann, 1903.)

For a consideration of the mechanism of the initiation of contraction in different parts of the heart of a typical vertebrate, see Goss (1937, 1938, 1940) and Copenhagen (1939).

Williams (1931) gives an excellent summary of development in this early period. The germinal stage of the human being may be considered to be the first week or two of life. The third week is thought of as the onset of the true embryonic period. At this period the medullary groove begins to be formed. A little later cell structures which make up the primitive heart are laid down and, as just noted, these cells begin the lifelong beat of the heart. At about this time, also, cerebral and optic vesicles begin to be differentiated and limb buds first appear. The muscles also develop rapidly in fine structure during this period.

In the second month there is continued morphological growth both in total height and weight and in the fine structure of the organs of the growing individual. Windle and Fitzgerald (1937) in a paper on the development of the spinal reflex show that all the elements needed for a reflex arc in the central nervous system are laid down during the sixth week but no spinal arcs are complete before the eighth week. Bolaffio and Artom (1924) note in this period that isolated limbs torn during delivery can be stimulated directly.

Minkowski (1920b) reports that at the end of the second month cutaneous stimulation elicits response. This finding is not confirmed by Bolaffio and Artom (1924), for they point out that at this time the skin is very thin and may involve in its stimulation the activation of receptors in underlying tissues.

Much is known of the structural and minute functional development of the receptors, nervous system, and effectors in this as in all later embryonic and fetal stages. It is not, however, until the fetus reaches the length of 15 mm, or is about 4 weeks old, so far as the writer can discover, that any direct statement can be made in regard to the activity of any

part of the response mechanism, and this is a negative statement. In a fetus of this length, Minkowski (1928b) reports that it was impossible to bring about muscular response even to an electric current of 40 milliamperes. He made observations on two fetuses of this length with the same conclusion.

This finding is not entirely unexpected, since Hewer (1927) has shown that histologically the musculature of the fetus develops at uneven rates, the unstriated musculature, which is the first to develop, being clearly formed in an embryo 1 mm in length. Striated musculature could not be detected in a fetus smaller than 2.5 mm long, and it did not take on its definitive characteristics in fetuses less than 22 weeks old. Special changes of structure are also noted by this same investigator in regard to heart musculature.

Possibly the youngest human fetus to be observed to move is one reported by Yanase (1907b) in his studies of the development of intestinal movement noted above. In a fetus 20 mm long and of an estimated age of 6 weeks, one movement involving the right arm is rather casually noted. The next youngest human fetus to be reported moving is a fetus 22 mm long and probably about 6 weeks old described by Strassmann (1903) in a case of extrauterine pregnancy. He observed through a rupture in the tube wall slow movements, backward and forward, of the arms and legs of the fetus. In evaluating this observation it should be noted that Strassmann's report is given in such a manner as possibly to lead to a questioning of his observations, since apparently the fetus was observed in such a way that rhythmic mechanical movement of the adult body was possible. Certainly all observers of fetal behavior have had difficulty in deciding whether or not they were seeing something which was not the result of passive external mechanical movement. It should be borne in mind, therefore, that possibly these two earliest observations should be substantiated before they are finally accepted. In a fetus of 30 mm, or an estimated age of 8 weeks, Minkowski (1923) observed a worm-like movement of the arms, legs, and trunk.

In Hooker's (1939b) description of his carefully controlled work the statement is made that no response to tactile stimulation has been observed before the eighth week of menstrual age. In a 25-mm fetus of a men-

strual age of 8 to 8½ weeks, however, response to tactile stimulation has been recorded. This same investigator has repeated this observation on two other fetuses of approximately the same age. At this stage tactile stimulation is effective only in the area over the mouth and immediately adjacent to that supplied by the mandibular and maxillary divisions of the fifth nerve. Hogg (1941) points out that the cutaneous nerves and nerve endings are very immature when responses are first elicited. No encapsulated endings are seen. Excitation is probably dependent upon deformation of the growing tips of the fibers by displacement of the surrounding tissue at this time, according to this author. Stimulation in this area in a fetus of this age led to contraction of the long muscles of the body and neck to produce body flexion. Limb girdle muscles related to both upper extremities were also activated. Rotation of the rump, caused by activation of the pelvic girdle muscles, was observed in very slight degree. Hooker notes that at this period a hand capable of exerting a pressure greater than 25 mg may cause direct mechanical stimulation. Faradic stimulation at this time is also effective. No spontaneous movements were noted by Hooker at or before this age.

Fitzgerald and Windle (1942) report that in a study of 15 fetuses 7 weeks to a little over 8 weeks old, fetal movement was seen in only three organisms. These responses were individual reflexes of trunk, arms, or legs when oxygenated blood was still supplied to them. For an excellent summary of the early development of human behavior see Hooker (1943).

Fetuses 9 Through 12 Weeks Old

In a fetus of 35 mm (estimated age 8 or 9 weeks) Minkowski (1928b) reports muscle contraction to galvanic current. Minkowski's work shows that fetuses of 40 to 50 mm (9 to 10 weeks) sometimes still show this characteristic muscle response, possibly without neural activation. The observation coincides with the observations noted above on the fetuses of lower mammals, in which the musculature comes to respond to direct stimulation before true neuromuscular action begins. The most elaborate studies of this sort of muscular response have been made by

Wintrebert (1904) (See also Minkowski, 1924)

Among the many significant observations that may be made at this period, it is interesting to note that the vestibular apparatus seems to be anatomically developed to its full (Minkowski, 1922)

A fetus of 42 mm was removed under operation by Woyciechowski (1928) to interrupt a pathological pregnancy. At the operation a mass was removed from the uterus. As soon as the mass was taken out, a fetus of 42 mm dropped from the excised sphere of tissue. This fetus, estimated by the operator to be of approximately 2 months' gestation age, was seen to move both arms and legs spontaneously. When it was touched by a finger an energetic "protective movement" began which involved a much stronger moving of the arms and hands and the opening of the mouth. The observations made upon the movement of this fetus were checked by another observer. In spite of cooling, the movements of the fetus lasted in an active form for more than 5 minutes.

In fetuses of the 9- to 10-week age period, Minkowski (1921b, 1922) noticed slow, asymmetrical, arrhythmic, noncoordinated movements. He also noted (1922) that at this time neurologically the elements of the spinal reflex arc are developed anatomically.

Bolaffio and Artom (1924) studied a fetus of about this same age. They report that dropping the fetus from a height of a few centimeters to a table led to active contractions of the flexor muscles of the limbs. Further, they noted that tapping the table lightly with the fingers elicited responses of energetic movements involving the elevation of the scapulas, movement of the arms, and flexion of the thighs and legs. These movements were elicited for about 3 minutes, after which they rapidly diminished in intensity and ceased. During the active period, stimulation by a blunt metal rod of the skin of the breast and of the abdomen led to no response. After the cessation of activity, direct brain stimulation led to no muscle response.

In a fetus less than 8 weeks old, Minkowski (1922) reports that percussion of the patellar tendon resulted in contraction of the quadriceps muscle. After this contraction had taken place, irradiation followed to other muscles. In this fetus the heartbeat was rela-

tively constant at 80 beats per minute, but covering the fetus with normal salt solution at 40° C led to an increase in the beat of the heart from a basal beat of 80 to 100 beats per minute. Extirpation of the cerebral hemispheres in this fetus did not change the reflexes described. Sectioning the medulla just above the cord region, however, abolished the reflexes due to change in the position of the body. In a fetus about 9½ weeks old Hooker (1944) notes that stretch of limb muscles is effective in stimulating proprioceptive organs and initiating response.

In a fetus about 2 months old, Bolaffio and Artom report that stroking and tapping elicited slow local contractions of all the muscles of the limbs. For example, if these stimuli were applied to the palm of the hand, adduction and internal rotation of the corresponding arm were noted, if to the leg, flexion of the corresponding thigh. These investigators state, moreover, that mechanical stimulation of the cortex in this fetus gave a constant movement of elevation of the left shoulder, but no contraction of either of the lower limbs or of the right shoulder. After this same fetus was decerebrated they note a greater vividness (*vivacità*) of the local contractions referred to above and the reappearance of diffusion of movement at a distance from the stimuli which had ceased. In this experiment mechanical stimulation of the medulla led to respiratory movements. They further suggest that even in a fetus of this age removal of the cerebral cortex does remove some inhibition from the lower reflexes. It is interesting to note that during this period the neural and muscular mechanisms basic to sucking are developed so that they may function. A study of the evolution of this mechanism throughout the rest of the fetal period is instructive. For suggestions, see Feldman (1920) and, for the later period, Liwin (1930).

Bolaffio and Artom report in regard to another fetus about 2 months of age that gentle stimulation of the skin of the whole body was followed by no response, but percussion led to definite responses. Definite percussion blows on the forearm sometimes led to flexion, adduction, and slight internal rotation of the arm. Percussion on any part of the lower limb led to flexion and adduction of the thighs with slight flexion of the

legs. If the percussion is rather light, the contractions are limited to the homolateral limbs, if somewhat more energetic, contractions also of the heterolateral limbs are reported. Percussion on the breast and abdomen gave homolateral responses about the pectoral muscles and bilateral responses about the abdominal muscles. Hooke (1944) reports that in fetuses of about 8 weeks the reflexogenous zone of the cutaneous surface of the infant spreads from a very localized area, including part of the upper lip and the skin about the nostrils, to the whole upper lip, chin, and part of the neck. The responses made at this time are stereotyped and mechanical in nature. That the fetuses are ready for such responses is shown by Windle and Fitzgerald (1937). These workers demonstrate that the elements of the reflex arc are laid down by the sixth week. Spinal cord arcs do not seem to be complete before the eighth week. It should be emphasized that Hooke (1944) says in commenting on this stage that "each stimulation in the reflexogenous area evokes a response which, within the limits of ordinary biological variation, is identical with every other one secured."

It is generally thought that even during the third month the cerebral cortex has as yet assumed no functions in relation to the general bodily activity. Bolaffio and Artom, however, report that removal of the cortex in a fetus of this age seems to remove inhibition from the reflexes of the lower limbs. This result is difficult for the writer to interpret. During this period sucking is theoretically possible, that is, the neuromuscular mechanisms necessary to bring about this response have probably already been determined. The reader who wishes a complete consideration of this earliest feeding reaction of the human individual should read the specific references given above to this reaction and then should refer to the summary of the knowledge of the reaction given by Feldman (1920). (See also Iwam, 1930.)

Arshavsky (1959) has pointed out that the function of the digestive system at various developmental stages are appropriate to the nutritive medium typically available at each age. He notes that the amniotic fluid enters the mouth and stomach in the fetal period. This fetal feeding reaction is con-

sidered as a necessary precursor to the taking of milk in early postnatal life.

After superficial and deep stimulation of numerous points on the body of a decerebrate fetus of 90 mm, Bolaffio and Artom at first recorded very vivid contractions of apparently all muscles. After about 3 minutes, however, the contractions were still bilateral, but limited now to segments and homologous regions of the body. As time passed, the contractions became more and more circumscribed, and after about 3 minutes they were limited to the muscles corresponding to the stimulated point. After 15 minutes every reaction had ceased.

During the third month Minkowski (1922, 1928a) reports labyrinthine reflexes, but Bolaffio and Artom (1924), obtaining the same responses that Minkowski reports, interpret them rather as responses elicited as the result of the stimulation of proprioceptors in the neck. Minkowski (1922) reports tendon reflexes at this age, but Bolaffio and Artom do not find them until the sixth month. Here once more the decision must be a very difficult one to make, if the writer may judge from his own observations on infrahuman fetuses. Stimulation at the locus of a tendon may lead to a response, but this may be due to several possible forms of stimuli, such as (1) cutaneous stimulation, (2) direct muscle stimulation, or (3) a true tendon-stretch muscle stimulation. Mere observation of the response makes very difficult the decision as to which of these forms of stimulation has been effective. Bolaffio and Artom's careful work, however, seems to indicate that at first muscle sensitivity dominates when the tendons are stimulated, but in later fetuses true tendon reflexes begin gradually to arise.

Golubeva, Shuleikina, and Vainshten (1959) have studied the neural basis of the development of motor activity from 16½ to 29 weeks of gestation. Every reaction studied such as grasping, sucking, sneezing show two phases in development. The first is a response directly related to the maturation of local and specific morphological structures. The second phase is that of an adaptive action and is due to the maturation of appropriate brain centers.

Hooke (1939a), in summarizing development during this period, says that by 9½ weeks of menstrual age responses include

rotation of rump and body flexion. The neck-trunk reactions are usually contralateral. At this period "spontaneous" human responses were first observed. This same investigator notes that from 9½ to 12 weeks a "total pattern" of response is dominant. At 11 weeks palmar stimulation causes a quick but incomplete finger closure, which marks the onset of the grasping reflex. Hooker (1938) studied the development of this reflex in great detail. He (1939a) further noted the onset of the plantar reflex during this period. Hooker (1944) also noted that by 11 weeks stimulative cutaneous reflexogenous zones have spread over the whole upper extremity, and the sole of the foot has also become stimulative. Patterned eye movements seem to begin at this time.

Fetuses 13 through 16 Weeks Old

By 13 weeks the top and back of the head alone remain insensitive (Hooker, 1944). Minkowski (1922), studying a fetus in the early part of this period (110 mm), recorded the fact that touching the lower lip or tongue with a blunt probe led to a closing of the mouth, brought about through the lowering and lifting of the jaw. He also noticed in the same fetus that reflexes of the trunk and extremities were seen prominently, but after the transection of the cord in the dorsal region the lower reflexes were discontinued at once. This seemed to prove that conduction of activation in this case, at any rate, was through the cord. After this operation, moreover, he noticed that the short reflexes remained unchanged but were themselves abolished after total extirpation of the cord. Destruction of the lumbar and sacral cord abolished the hindlimb reflexes, whereas similar destruction of the cervical cord abolished those of the forelimbs.

The so-called spontaneous movements observed by Hooker at 14 weeks include the activity of most body parts as well as of the "organism as a whole." For the first time these movements, like those at about the same period elicited by tactual stimulation, may be characterized as "graceful" and delicate." Hooker (1944) points out that by this period, except for movements of respiration and vocalization and the true grasping reflex, the fetus already shows most of the responses that can be elicited in the neonate.

In a fetus of 135 mm Minkowski (1922) notes that a touch on the skin, using a blunt stimulus, led to reactions of diverse parts of the body. Characteristic of such stimulation were the flexion of both arms, the repeated opening and closing of the mouth, and simultaneous retraction of the head. He notes that at this stage of fetal development every part of the skin can act as a reflexogenous zone for various reactions. These reactions, however, tend to spread more or less over the entire fetal organism. Direct muscle excitability still remained at this stage 1 hour after the cord had been extirpated. Total removal of the cerebral cortex did not change the observable responses noted above. Transection at the midbrain, however, seemed to weaken the responses, although they still continued.

In a fetus 160 mm long Minkowski (1922) reports spontaneous dorsal flexion of the great toe, although he could secure no direct response to the touch of the sole of the foot. Distinct contractions of the abdominal walls were evoked in this fetus by brushing. Touching the closed eyelid in this fetus evoked a contraction of the orbicularis muscle.

Eibkam (1837) reports a study of a fetus, accidentally delivered, approximately 170 mm long. He noted the contraction of both arms and legs and the movement of the head from side to side, "as if to breathe." In this fetus the heart beat for 10 minutes. After that time the water in which the fetus was lying became cool and the heartbeat became slower. When more warm water was poured in, however, the heartbeat became lively. The eyes of this fetus were closed. The great physiologist Johannes Müller saw the fetus and agreed with the author that it was of approximately 4 months' fetal age.

In a fetus of 180 mm Minkowski (1923) noted spontaneous movements of all the extremities and the head. These were noted before the umbilical cord was ligated. In this fetus, touching the sole just at the time of delivery led to the dorsal extension of the big toe, the Babinski reflex. Later the plantar flexion followed (1923, 1928a).

In a fetus 190 mm long Minkowski (1924) obtained definite indication of reciprocal muscle innervation. He also reports at this stage that diagonal reflexes were established, that is, stimulating one foot of the fetus would

lead to the movement of the arm on the opposite side. In certain instances the stimulation of the sole of the foot on one side even led to the movement of one finger, the little finger, on the hand of the opposite side of the body. These diagonal reflexes are considered by Minkowski (1922) as significant in relation to the trotting reflex.

This elaborately patterned series of movements, as has been noted, is an especially basic constellation of inborn responses in mammalian and also in submammalian vertebrates.

During this period the sole of the foot reflexes are thought by Minkowski (1928a) to have their connection in the spinal cord and the tegmentum. In terms of response this involves the domination of the response of extension over flexion. (See also Dewey, 1935.) For a photographic sequence of the foot reflexes of a 14-week fetus, see Fig. 18, from Hooker (1939b). Liesch (1946) has described the stimulation of mucous membrane areas and other cutaneous areas in a fetus 200 mm in length and of an estimated age of 4 months.

Fetuses from 17 Weeks to Normal Birth Time

In experiments previously referred to, Baicroft (1938) has shown that after about one-third of the normal fetal period has passed in the sheep a remarkable change takes place. At this point the organism, which has already developed most of the basic patterns of behavior, becomes more quiescent. Spontaneous movements decrease. This is due to the fact that at this time a less adequate supply of oxygen is provided for the fetal central nervous system. At about the sixteenth week Hooker (1944) notes that a similar sluggishness begins in the human fetus. This again gives emphasis to the fact that in the study of the fetus positive evidence that such and such a response can be elicited is much more important than a negative finding when one is seeking for the neurological correlates of behavior.

In several fetuses approximately 200 mm long, that is, about 17 weeks old, Minkowski found that brushing the sole of the foot led to plantar flexion of the toes, except the big toe, which did not move. This was directly related to Minkowski's elaborate study of the reflexes of the sole of the foot. (See 1922,

1923, 1928a.) Direct mechanical stimulation of the motor roots of the spinal nerve at this stage showed that intersegmental spinal conduction is well established (1922). Mechanical stimulation of the cranial nerves at the level of the medulla led to the opening and closing of the mouth. It is presumed by Minkowski that this reaction resulted from the direct stimulation of the facial nerve. At this period direct stimulation of the cortex does not lead to response (Bolaffio and Aitton, 1924), but breathing changes do result from stimulation of the medulla.

In a fetus of 210 mm Minkowski (1922) observed opening and closing of the mouth accompanied by arm movements. The duration of such movements at this period was limited. Maximum responsiveness seldom lasted more than 1 minute at the most. In a fetus of 230 mm Minkowski noted for the first time continued rhythmic contractions of the sort often described as Ahlfeld's breathing movements.

In a fetus of this same length Bolaffio and Aitton (1924) noted that by employing superficial stimulation they were able to elicit localized muscular contractions in the limbs and other specialized muscle groups. By using strong and deep stimulation on a single segment of one limb, it is possible to elicit flexion of the whole contralateral limb. They also noted that stroking the ridge of the tibia gave vivid adduction of the homolateral thigh. In regard to the development of cortical dominance at this time it is interesting to note that mechanical stimulation of the Rolandic zone of the brain, either through the cranial cap or after its removal, did not call forth any reaction. Nevertheless, removal of the hemispheres did lead to more vivid local responses than in preceding excitations when the brain was intact. Stroking the pectoral muscles called forth adduction of the contralateral limb. In this case also these investigators reported that, if the intensity of the stimuli was increased somewhat, they got contraction of the whole corresponding limb. By stimulating the medulla they were able to call forth violent respiratory movements with active participation of the cervical, thoracic, and abdominal muscles, and those of the diaphragm. These movements were so violent they also led to elevation of the shoulder and adduction of

Fig 18 Response to tactile stimulation of the sole. Probable menstrual age 14 weeks. Stimulation was applied by stroking the sole of the right foot with a 2-gram hair (1). The response consisted of the following elements, (a) Extreme dorsiflexion of the hallux (2 to 4) and "fanning" of the other toes (3 to 6). The toes, other than the hallux, ultimately show slight plantar flexion (6 and 7). (b) Flexion at the hip (2 to 4), slight flexion at the knee (3 to 5), and slight dorsiflexion of the foot (2 to 4). (c) Return to normal posture (5 to 8). (From Hooker, 1939.)

the arms. It is further significant to realize that these investigators found, after repeated successive experiments and as the vitality of the fetus became less, that the muscular contractions disappeared first in the lower limbs and then later in the upper limbs.

In a fetus of 240 mm Krabbe (1912) reported slow movement of the limbs and contraction of the muscles as the result of percussion. He also obtained strong abdominal reflexes as the result of light blows. The plantar reflex occurred without involving the

participation of the big toe. In the fetus that he investigated the heartbeat was strong and he was able to elicit a number of reflexes, the abdominal reflex being especially strong. The fetus was a female, but he was unable to elicit the female cremasteric reflex. He felt that both bone and tendon reflexes were present and was able to demonstrate that direct muscle stimulation was possible.

In a fetus of 260 mm Bolaffio and Artom (1924) attempted certain specific neurological experiments. By means of appropriate electric stimuli they explored the cortex but did not obtain any reaction even with intense stimulation. By operation the internal capsule and peduncles of the brain were exposed, but still electric stimulation gave no response. When they reached the pons, however, they got ready and synchronous responses from the muscles innervated by the facial nerve. Finally, stimulation of the medulla gave energetic respiratory movements. Stimulation of the cervical cord led to energetic movements of elevation of the shoulder with flexion of the upper limbs, and stimulation of the lumbar cord gave movements of the lower limbs.

In a fetus 270 mm long Minkowski (1922) noted that from the first the plantar flexion of the toes was present to stimulation of the sole of the foot. Minkowski is of the opinion that at this age the plantar flexion must still be considered as a pure spinal reflex.

In a fetus of 280 mm Minkowski was able to bring about rather elaborate but quite well-differentiated muscular responses to a single electric stimulus. For example, the muscles of the eyelid could be activated with great specificity. After exposure in an this fetus is reported to have made faint sounds. These sounds are possibly the earliest observed in a human organism. They may be taken by those who are interested in zero points as the onset of functional activity in the great mechanism which makes human speech possible.

In a fetus of the same length Bolaffio and Artom (1924) observed that every muscle reacted even to quite energetic stimulation, such as percussion, by local contraction. This specificity is more marked in the head region than in the leg region of the fetus. Percussion in front of the ear led to a movement of closing of the eye with eleva-

tion of the angle of the mouth and chin. Strangely enough, however, it seems that the deep reflexes are not easily obtained at this age in the arms. Stimulation of the legs shows that the patellar reflex can be called forth bilaterally and the Achilles tendon reflex on one side. No plantar reflex was elicited in one fetus at this age.

In a fetus of 310 mm Bolaffio and Artom further reported the observation of periodic respiration. Breathing was "by fits and starts." The heartbeat was regular. At this period all the muscles of the limbs can be excited one by one with percussion, obtaining vivid reaction. Appropriate local stimulation serves to bring out most of the typical percussion reflexes, including minor responses of the fingers, of the toes, and of the sole of the foot. The plantar reflex, however, and some of the others, still seem to be absent.

Generally in the sixth month there is an increased tendency of various receptor-neuromuscular mechanisms to act independently, and this independent contraction is part of the greater vividness of response which characterizes this period as contrasted with earlier periods. Bolaffio and Artom find in this month for the first time tendon reflexes which seem to be assuredly not the result of cutaneous or muscle stimulation. Then judgment on this matter is based on the facts that the specific responses given at this period are not found before this time but continue to increase in strength during the later fetal periods, and that they are the same responses which are elicited in early infancy as true tendon reflexes. Direct stimulation of the mouth and tongue at this age elicited the sucking reflex, according to Bolaffio and Artom. In older fetuses stimulation of the lips alone leads to sucking movements which may or may not be accompanied by the protrusion of the tongue. As noted, Minkowski found this reflex at an earlier period.

These same investigators, using a slightly larger fetus (330 mm), again reported superficial respiratory movements. These breathing reactions ceased after a minute or two. They reappeared when pressure and percussion of the thorax were used. In this fetus they noted also that with percussion the muscles gave powerful and localized contractions. The tendon reflexes which could be elicited included those of the biceps

and triceps and the Achilles reflex. Direct stimulation of the cortex still brought no response. In this fetus it seems that no true cutaneous reflexes could be called forth either before or after the removal of the brain. In another fetus of exactly the same size these same investigators report that the fetus cried weakly and moved about spontaneously but with less strong movements than those characteristic of a fetus at term. When death seemed imminent in this fetus the top of the skull was removed and the cortex directly stimulated electrically. All the various zones of the cerebral cortex were stimulated with negative results. Stimulation of lower brain centers, however, led to specific results such as increased breathing rate, shoulder, arm, and finger movements.

Bolaffio and Artom also reported the behavior of a fetus of 340 mm which appeared to be slightly undernourished. This fetus made weak crying sounds and breathed weakly. After about 2 hours it stopped breathing. During the period before breathing stopped they elicited contractions by tapping one by one the muscles and groups of muscles of the body. In this specimen by stroking the sole of the foot the plantar flexion of the toes was brought out. All these reactions became more vivid just before the death of the fetus. This suggests a change in the higher brain centers as a result of a lack of oxygen.

Certain responses noted in the seventh month, although definite, nevertheless are seen to involve synergic muscle groups (Bolaffio and Artom, 1924). This finding must be taken into consideration in evaluating statements given in regard to the randomness of activity in the newborn child. It may well be that much of the apparent "mass activity" of the newborn child (Lewin and Weiss, 1930) is not truly diffuse response of the sort found in the early fetus, but rather the activation of groups of synergic muscles in the sense of the term as used by Sherrington and his associates (Creed, Denny-Brown, Eccles, Liddell, and Sherrington, 1932). Klabbe, Minkowski, and Bolaffio and Artom all report abdominal reflexes at this period. A number of other specific reflexes are also clearly brought out at this time. The knee jerk is definitely elicited. The plantar reflex, according to Minkowski, now

probably involves not only the centers concerned during previous months but also part of the lenticular nucleus and the red nucleus. Bolaffio and Artom feel that at this period the plantar reflex in its typical form is much like that of adult life but that it is still much more variable than it will be at a later period. This leads them to be critical of statistical work on reflexes, such as that of De Angelis (1922) (Cf. also Cesana, 1911). The corneal reflexes are seen in the seventh month. Direct stimulation of the cornea of the eye leads from this time on to an increasingly strong response. Decerebration in this month was found to lead to increased vividness of most reflexes, but also to a tendency to reflex spread.

In a still larger fetus Bolaffio and Artom reported that with slight percussion of all the muscles of the limbs they observed vivid responses not limited to single muscles. Such responses spread to synergic muscle groups. With percussion of the pectoral muscles they obtained adduction and internal rotation of the arm and flexion of the forearm. They obtained bilaterally the patellar reflex and an extension of the leg, sometimes associated with flexion of the thigh. Associated with this pattern of response was the dorsal flexion of the foot. The Achilles tendon reflexes, however, were not always obtained even in a fetus as old as this one. These investigators also failed to get abdominal reflexes in fetuses of this age. However, the slight excitation of the sole called forth a definite unified toe phenomenon, and then a more energetic stimulation called forth flexion of the toes. The sucking reflex was secured only by stimulating the tongue. They reported that the movement of grasping which they got by applying pressure to the palms of the hand was energetic. These same investigators reported that from the seventh month to birth they investigated 13 fetuses of 7 months, 3 of 8 months, and a large number of mature fetuses. In this study they have not considered protocols of any fetuses which, because of condition of nutrition or on account of the presence of disease, did not present normal situations. They assert that from the end of the sixth month the movements of the fetus became so powerful and complex as to render very difficult and some-

times impossible detailed and specific report of behavior

During the last two months of pregnancy the muscular reflexes decreasingly tend to prevail over the tendon reflexes, according to Bolaffio and Artom. By the end of the ninth month the tendon reflexes are so well established that they prevail over special muscular reflexes. All the tendon reflexes are found to be present during this period of fetal life, with the exception of those of certain of the upper limbs which are elicited with difficulty because of the small size of the member. Contralateral adductor reflexes are sometimes called out in this period. Even in the fetuses nearest term, the cremasteric reflex was difficult to elicit (Bolaffio and Artom, 1924).

At any prenatal age, including this last period, however, it is noticed that very light stimulation of the hand gives variable and inconstant movements, whereas strong stimulation, possibly involving the muscle or other underlying tissue, leads uniformly to grasping (Bolaffio and Artom, 1924). Bolaffio and Artom, therefore, believe that the grasping reflex is not to be thought of as a purely cutaneous reflex in prenatal life. Minkowski (1928a) finds this reflex at an earlier period. Iris reflexes are present during the prenatal period (Bolaffio and Artom, 1924). The reaction of the iris, however, is slow, and very strong light is needed to call out the response. (See also Minkowski, 1928a.) It is difficult to say when the response would begin if stimuli as strong as direct sunlight could always be used. Bolaffio and Artom do not note the fact, but it seems obvious that, with such strong stimulation as they recommend, the danger of independent muscle effector action of the sort described by Parker (1919) must be guarded against.

There is some evidence that the cerebral cortex is directly stimutable at this period, although as yet the evidence is not conclusive (Bolaffio and Artom, 1924), as will be pointed out later in considering the possibility of fetal learning.

General Characteristics of Fetal Behavior

It is possible to add to this consideration of month-by-month fetal development some general statements that have been made by those who have been most directly concerned

in these investigations. Thus Minkowski holds that one may say that every part of the skin can, as its receptivity is progressively established, serve as a reflexogenous zone for quite variable reactions which tend to spread more or less over the whole fetal organism. In the whole developmental process the gradual acquisition of postural responses and muscle tone is peculiarly important. The development of these responses will be considered in the section in which the origin and development of the proprioceptive and static senses are discussed. Minkowski offers in part explanation of the spread of reflexes during the early periods the fact that the spinal cord tracts as well as the nerve trunks have no medullary sheaths before the fourth month of fetal life. Illustrations of Minkowski's anatomical work on the nervous system are given in several places (1921a, 1928a). There is a suggestion that from this time on there is an anatomical increase in specificity correlated with the differentiation of the nervous elements in ways possibly involving the nature of protoplasm, neurofibrils, medullary sheaths, synapses, long conduction paths, and other cell changes (Minkowski, 1922). These gradual alterations in the nervous system, it is suggested, lead progressively to the possibility of more and more circumscribed and definite response. Compared with the diffuse character of early fetal response, therefore, in the late fetus, Minkowski (1920a) feels that all the well-known special reflexes have more or less been established. The preceding discussion, however, has shown that the process of development of these reflexes is a complex one and that later in adult life injury to the nervous system may bring about reactions which were characteristic of a previous period, even of a fetal period (Minkowski, 1922). For the historical breaking of ground in this connection, see H. Jackson's essay (1884) on the evolution and dissolution of the nervous system. For a consideration of the psychological development of the fetus see Minkowski (1947-1948, 1962).

It must be impossible to read what has gone before in this chapter without realizing that there is a general relationship in sequence of development of behavioral capacities from fish to man. It must be noted, however, that there are peculiar dangers in generalizing from, for example, the amphibian

development of behavior, or even the rodent or cat development of behavior, to the growth of adaptive actions in man. For example, it has been shown clearly that in fish, amphibians, and lower mammals the first responses involve a unilateral bending of the trunk. This stage may or may not exist in the human individual, but at any rate no observations have so far been made in which trunk movements unaccompanied by arm movements are observed in early fetuses.

The basic pattern for the development of locomotion and other "individuated" responses, as suggested by Coghill and his students, may be seen in a less typical form in human development than might be supposed, although Coghill (1929c) himself has called attention to the attractive possibilities of the analogy. Little evidence of rhythm in the limbs of the human fetus has been determined. It may well be, therefore, that locomotorlike movements of the limbs do not appear until very late in the human fetal period. Windle and Griffin (1931) have summarized this comparative evidence, and they suggest that the movements observed in the kitten fetuses with which they have worked possibly should not be compared directly to human fetal movements because of the differences between the two in the type of adult locomotion. In a similar way the locomotor mechanisms in fish and amphibians which require a high degree of trunk-muscle integration may be difficult to compare with the conditions obtaining in a mammal that stands erect.

Too much emphasis cannot be placed upon the fact that easy generalizations, such as the assertion that all behavioral development occurs from a generalized total pattern of the organism to the specific responses of adult life, must be taken with great caution. While this description may be true in many respects, particularly if the word "pattern" is given an unambiguous meaning, it seems certain on the basis of the specific responses considered above that it cannot be indiscriminately applied. Before generalizations can be made with assurance, there must be a large amount of accurate measurement and the determination of a series of statistical norms in regard to the development of each of the specific developmental stages in each form considered. Typical cross sections in

development in every form and in all responses from significant receptor surfaces must be considered before such a generalization can be made. Certainly the late fetus has an elaborately organized and in some respects quite specific response mechanism. To some stimuli the relatively early fetus makes quite definite responses.

It seems hard to believe that anyone who knows anything of the structure and function of the tracts and centers of the central nervous system can read the report of fetal activity at various developmental levels given above and still feel that there is much to be gained by saying that before birth the organism reacts as a whole, as certain psychologists, possibly under the influence of one form of the *Gestalttheorie*, have suggested. Much of the nervous system may, in some sense, be involved in any partial activity of the system, but this does not mean that the system is not in many respects sharply differentiated. Certain essential relationships between diffuseness and specificity and between individuation and integration of behavior will become clearer after the parts played by the specific senses in fetal life have been considered.

The account presented above from the reports of several investigators gives a picture of the development of behavior in human fetal organisms of estimated ages. No effort has been made to include all known published accounts of fetuses but only those in which behavior significant for the general problem of this chapter was noted. Minkowski (1923) refers to at least 11 fetuses not considered here in which primarily the only reflexes studied were those released by stimulation of the sole of the foot. In the study of this response Bersot (1918, 1919, 1920, 1921) has also considered fetal activity in detail in relation to a study of the development of the clinically significant plantar reflex. This same response has been considered from a scientific and theoretical point of view by Feldman (1922) and by Minkowski (1926) in work that has been referred to above. For an account of a fetus investigated by Winterstein, see Minkowski (1928a).

Hooker has given permission to refer to his *Preliminary Atlas of Early Human Fetal Activity* (1939b), which was issued for restricted use only. Reference previously has

been made to this work, but the author wishes to call special attention to it because it contains very beautiful reproductions of photographs of human fetal material 8½ to 14 weeks of menstrual age. A careful study of this atlas may give a more adequate picture of early human fetal behavior than any other single reference known to the present author. Milner (1967) has presented an outline of pattern of prenatal neural and behavioral development that should be consulted in this connection.

THE SPECIAL SENSES IN HUMAN PRENATAL LIFE

Historically there has been much speculation in regard to the role of the senses before birth. In earlier psychology these speculations centered largely about the question of whether or not some sort of dim conscious awareness exists in the infant before birth. More recently this essentially non-experimental question has given place to one that may be studied. The question now asked is: How and when does the stimulus control of fetal behavior determined by the activation of the various receptor systems begin before birth, and how do behavior capacities develop? Objective techniques for study of the senses in the premature or newborn infant have been devised, of which those of Canestum (1913) and A. P. Weiss (1929) are significant examples. These techniques have not only made quantitative study of the senses possible in a new way, but they have also added to the general knowledge of the part that stimulation plays in the subtle alterations of bodily activity. In this chapter, therefore, the various specific senses will be considered in turn in relation to fetal behavioral or mental life when such behavioral or mental life is considered as including not only experience but also specific receptor-controlled behavior.

After each of the senses has been treated, some generalizations will be made by the author on the significance for psychology of receptor-aroused activity in the fetus. The reader should be reminded that the material presented above on the development of the senses in lower animals and especially the elaborate work on the guinea pig has much relevance in a consideration of the growth

of the human senses. In this section, however, the whole emphasis is placed upon human development except where specific reference to infrahuman forms is considered necessary for strictly comparative purposes. Of all the traditional topics of scientific psychology, it seems that perception may have most to learn from a proper comparative study of fetal and neonatal senses.

Perception

In the study of perception there has been a long debate between those who believe in nativism (the idea that ability to perceive space, movement, time, objects, and related aspects of the "external world" is inborn and not dependent on individual experience) and empiricism (the idea that such perceptions originate in individual experience or learning). Modern study of receptor mechanisms shows in detail how external environmental energies activate sense organs. This activation leads to the release of coded impulses in the sensory nerves associated with such receptors. Coded messages then pass into the central nervous system and initiate other coded processes which ultimately, in typical cases, lead to adaptive adjustment on the part of the total organism by activating its appropriate effector organs. The point to emphasize here is that the effect of the environment on the organism is transformed into coded information in the receptors and in sensory or afferent neurons. Broadbent and others (1961) present a good case for preferring the language of information flow to that of stimulus and response in his consideration of human perception and animal learning. As mentioned elsewhere in this chapter, adaptive or even maladaptive relationships to its environment may thus be thought of as a result of muscular or glandular response to coded information about the external world. Perception thus can be viewed as a result of neural (including neurochemical) activity which was started by coded inputs. The central neural processes (molar or molecular) which are involved in this activity are a result of the evolutionary processes that have led to the origin of the species in question and thus make the adaptation of that species to its environment possible. Present behavior of the sort involved in perception thus partly depends on molar

or molecular mechanisms that are genetically determined. Specific responses of each individual at certain ontogenetic stages lead, as a result of learning, to specific perceptual responses that are empirically acquired.

The old arguments between supporters of nativism and empiricism were largely discussed before some of these modern facts about the physiology of the sense organs and the nervous system were known. It is not by accident that the man who is sometimes called the first modern physiologist, Johannes Müller, is generally considered as having "given formal status to the nativistic theory in 1826" (Boing, 1942). Müller and Sir Charles Bell (Carmichael, 1926a) are properly considered as the scientists first to explain the phenomena basic to the idea of the so-called "specific energies of nerves." This view of neural action is the precursor of our modern knowledge about coded sensory inputs. As Barlow (1961) well says, "There are two encouraging results of considering the operation of the sensory side of the nervous system as a reversible code: for removing redundancy. One is that this is a subdivisible operation and so could be brought about by the large number of semi-independent units which appear to make up the central nervous system, the other is that mental acts, when broken down in this way, may be reduced to a level of simplicity which can be understood and investigated by the physiologist."

Arguments about nativism and empiricism in perception, however, are by no means all history. Some of the modern work in this field shows the great importance of a study of fetal and newborn organisms in understanding the psychology of the newborn and indeed the adult human individual. Bishop Berkeley, in his famous *An Essay Towards A New Theory of Vision* (1709), is generally credited with establishing the view that perception (such as that of visual space) is dependent not only on the eyes but also on touch. Berkeley's view is well summarized by Pastore (1965). Berkeley, as noted by Pastore, asserted, "Consider, for example, a globe as the first object within reach of an infant. The visual sensation is a certain gradation of colors in the same plane in conjunction with that sensation, the infant extends his arms and feels the rotundity of the globe. After many trials, the visual

sensation serves as a sign (or suggests) the tactual idea of palpation of the globe. The infant will thus have the perception of solidity even when touch is prevented."

This empiricistic or "learning theory" of the visual perception of space has had many proponents down to the present day. But as Pastore has clearly shown, it was essentially disproved more than a century ago by Samuel Bailey (1842, 1855). Bailey pointed out that the behavior of newborn mammals offers a better test of Berkeley's theory than does a study of the newborn human infant. Bailey (as paraphrased by Pastore) says, "The infant, in being born 'helpless' does not have the necessary 'organic maturity' of senses and limbs then development is one of 'gradual growth'." Bailey then goes on to discuss the fact that animals born or hatched in a relatively mature state (in the terminology of this chapter, "precocious" animals) have essentially identical optical structures with those of man. Bailey then further points out that immediately after birth, such precocious animals can run about, snatch at objects and leap from one spot to another with the greatest precision and without learning.

The present author has made many similar observations on newborn mammals. A newborn guaffe, for example, a few minutes after birth, can, without any trial and error, visually localize a sound at a distance and show other types of immediate adaptive visual perception (Carmichael, 1957). The admirable experimental work of Eleanor J. Gibson and her associates (1960) on the visual cliff contributes very important evidence on the matter. She says, "From our first few years of work with the visual cliff we are ready to venture the rather broad conclusion that a seeing animal will be able to discriminate depth when its locomotion is adequate even when locomotion begins at birth. (See also J. Gibson, 1958.)"

The present author's work on the development of "local sign" in the tactual perception of space in fetal animals similarly points to the correctness of a nativistic view of perception (Carmichael, 1961).

Before leaving the early work of Bailey and his refutation of Berkeley and the other older empiricists, it is interesting to note that John Stuart Mill went out of his way to attack Bailey for an odd but possibly significant

reason Mill was a social reformer as well as a great psychologist and economist. He wrote in relation to Bailey's work and that of another nativist, Sir William Hamilton, "the prevailing tendency to regard all marked distinctions of human character as innate, and in the main indehble is one of the chief hindrances to the rational treatment of great social questions and one of the greatest stumbling blocks to human improvement" (quoted by Pastore from Mill's autobiography).

In the present author's opinion the last word on this socially important question has not been written but the work of Bailey each year seems more surely correct. A rational consideration of what is really innate in human nature, with all its implications for "the rational treatment of great social questions," still needs active study.

The Cutaneous Receptors

In a consideration of the senses of touch, an effort is made to suggest such differences as have been noted in fetal life between light and deep pressure, temperature, and cutaneous pain. The development of skin in the human fetus has been anatomically described by a number of writers. This work is summarized by Feldman (1920). In appearance the skin of the late fetus or early premature infant is very red, owing to the visibility of the vascular system just beneath it. At 2 or 3 months before birth the skin is still quite thin and is covered with *lanugo hairs*, which appear at about the fifth month of pregnancy. The skin of the fetus during mid-pregnancy is typically much wrinkled, because of the comparative absence of subcutaneous fat. The hair on the scalp at this period is short and poorly pigmented. The nails grow gradually during late fetal life (Hess, 1922).

There has been much speculation on the skin as a sensory surface during the uterine life of the fetus. Cabanis is quoted by Genzmer (1882) as holding the skin to be a peculiarly important receptor field at this period. Bichat (1827) and Magendie, as noted above, discussed the skin sensibility of the fetus. Some casual observations are also reported in relation to the material summarized previously in this chapter concerning the possibility of stimulating the fetus by pressing on the abdominal wall of the mother. Of course, stimulation of this sort may well activate the deep-

lying proprioceptors as well as the true tactile receptors. In the review of the literature in the experimental study of the development of fetal behavior in infrahuman organisms, many references have already been made to tactual stimulation. In the human field alone, Minkowski, Bolaffio and Artom, Kiabbe, Hooker, and others have considered fetal responses that are released by cutaneous stimulation as indicated above. Hooker has been especially careful to use quantified stimuli. The part played by the sense of touch in animals and man in discrimination and even in responses of equilibration is considered by Kidd (1907).

A Pressure. In summarizing the work that has been done on human and infrahuman fetuses, the following factors may possibly be isolated as important in a consideration of the pressure sense before birth.

1 Place Stimulated. In general, cutaneous sensitivity seems to begin in the oral-nasal region, that is, the region involving the mucous membrane of the nostrils and the red of the lips (Genzmer, 1882, Windle and Giffin, 1931, Hooker, 1944). In rodents the pads of the vibrissae also very early become sensitive (Lane, 1917, Raney and Carmichael, 1934, Carmichael, 1934a), and in many animals the regions about the eyes and the openings of the ears are also very early sensitive, as is the anal region (Coromios, 1931). In the human infant Kussmaul (1859) found the eyelashes very sensitive, but this was not confirmed by Genzmer (1882). Most studies seem to suggest that, with individual variations, skin sensitivity develops by spreading out over the face region and then progressively over the surface of the body. In this development in certain organisms, such as the toadfish, the salamander, the rat, and the cat, a fairly well-worked-out course of temporal difference in the arrival of sensitivity in increasingly caudal segments of the body may be observed. In animals with tails this even goes on out to the end of the tail.

In this general course of development, however, certain exceptions have been seen, as noted above by the writer in a study of the development of the receptive zones of the fetal guinea pig. Sensory development in general has been treated by Minkowski and other investigators as the spreading of what they have termed reflexogenous zones. This term has much to recommend it because at present

almost the only method used in the study of fetal sensory capacity on the skin is the recognition of behavior correlated with the experimental stimulation. Windle and Griffin (1931) suggest in general that motility precedes the ability of a part to be stimulated. In his consideration of the "reflex circle," Holt (1931) has suggested the large part that self-stimulation may possibly play in the development of specific forms of behavior as organisms develop. Certainly no one who has watched an active mammalian fetus can help being struck by the fact that in its movements it stimulates almost its entire body surface by its own moving paws and head. It is peculiarly striking to watch a 48-day guinea pig fetus, for example, stimulate its head and face by appropriately cupped "hands." These scrubbing movements, performed not once but over and over again, are such that the surface must certainly be irritated by the friction.

2. Areal versus Punctiform Stimuli Minkowski (1922), Coronios (1931), Windle and Griffin (1931), Carmichael (1934a), Raney and Carmichael (1934), and Hooker (1936) have all apparently noticed that stroking produces stimulation when single punctate stimulation does not bring about response. Following this suggestion, Raney has been able to show that stimulation of a point on the skin by a single hair may not bring about response, but stimulating the same area immediately around such a point with a brush made up of comparable hairs will sometimes do so. (In this connection, see also Kuo, (1932e).)

3 Summation of Stimuli Carmichael (1934a) and others have noted that a single touch with a light hair may fail to bring out response, but several touches apparently of the same intensity at the same point may be effective in eliciting response.

4 Weak and Strong Stimulation Genzmer (1882) long ago noted that in a premature infant entirely different responses might be elicited to weak and strong cutaneous stimulation. The distinction in terms of the strength of cutaneous pressure is one that has too infrequently been made in studies of fetal development. Thus, as previously noted, Bolaffio and Artom disagree with Minkowski as to the point at which cutaneous reflexes begin in the developing fetus. This disagreement may be based on the fact that Bolaffio and Artom

(1924) indicate the possibility that Minkowski was unwittingly stimulating the underlying musculature and thus that the massive responses which he reports in young fetuses are not cutaneous but are due to the stimulation of deep receptors. The possibility of direct muscle stimulation in such cases must also be remembered. Holt (1931) considers that the distinction between strong and weak stimulation is a peculiarly important one in the development of the functional activity of the growing organism. He believes that light stimulation will usually lead to response moving toward the stimulus, or *adiently*, whereas only secondarily does strong stimulation of the same receptor field lead to *abient*, or withdrawal and avoidance, responses. Richter (1925) and others have confirmed this observation. Indeed, Coronios, Schlosberg, and Carmichael (1932) have been able to take moving pictures showing exactly this response as the result of stimulating the paw of a fetal kitten.

Under other circumstances, however, observations have not been such as to confirm this generalization. Thus Coghill (1929a) asserts that the first responses of *Amblystoma* are all away from the region stimulated. Windle and Griffin (1931) point out that the unilateral trunk or neck flexions of the earliest fetuses seem to be executed toward the observer and away from the surface on which the animal is resting. Kuo (1932e) also uses the strength of the stimulus as a peculiarly important part of the theory of development which he has proposed. It seems possible that in responses in which apparently the same receptor field is stimulated first lightly and then more strongly two distinct neural mechanisms may sometimes be brought into play. It might be suggested speculatively that the facts behind the differentiation between the allegedly developmental epicritic and protopathic sensitivity, as proposed by Head and Rivers and especially as explained by Boring (1916) and later by Sharpey-Schafer (1928), will ultimately provide some clue in the explanation of this diversity of response to different stimulus intensity.

Windle and Griffin (1931) also discuss a developmental system of cutaneous receptor mechanisms. The difference in responses to light and heavy tactile stimulation makes peculiarly uncertain the interpretation of results

of investigators who do not indicate that they have considered the strength of the stimulus as important in describing the fetal responses which they have elicited in experimental work. It is all the more peculiar that this distinction should not have been continuously made, because of the statement in regard to the difference in responses to weak and strong stimuli made, as noted above, many years ago by Genzmer. As previously reported, Smith and the writer (Carmichael and Smith, 1939) have demonstrated a quantitative relationship between the extent and spread of response and the intensity of punctiform stimulation when calibrated esthesiometers were used.

5 Localization Preyer (1882) believes that the first localization response to tactile stimuli is the seeking of the nipple by means of the cutaneous stimulation of the lips. Many specific references have been given above to the motor responses of various fetuses set off by tactual stimulation. It has been suggested in connection with the work of Raney and Carmichael (1934) that such responses possibly develop greater accuracy in localization as age progresses.

6 Cutaneous Reflexes As suggested in the preceding paragraphs, the skin may be thought of as a mosaic of points, each spot of which is the locus of stimulation for a more or less specific behavioral response. Many writers have discussed the significance of cutaneous reflexes in adult life. Givley (1921) has suggested the wide significance of the development of one such reflex, that of grasping. Hooke's (1938) careful observations on the grasping reflex show that it develops during fetal life in two phases: finger closing, and gripping. Finger closing appears as a quick flexion of the digits except the thumb at about 11 weeks of menstrual age. Gripping is first observed in the eighteenth week. It is still weak in the twenty-fifth week of menstrual age. In the first 25 weeks of fetal life the thumb seems to play no role in fetal grasping.

Minkowski, as noted, considers in detail the variations in the pattern of the reflexes elicited by the stimulation of the skin of the sole of the foot. Sucking, in its later stages, is possibly conditioned by a number of exteroceptive and interoceptive stimuli, such as the stomach contraction of hunger, but it is in essentials

always a cutaneous and mucous membrane reflex. The cremasteric reflex and certain of the abdominal reflexes also result from stimulation of the cutaneous field. In a paper on reflex sweating in the fetus, it is pointed out that human sweat glands can be seen in the palm and sole of the foot by the sixteenth fetal week and in the axilla by the nineteenth week. The secretory activity is established late in fetal life (Higashihara, Hirasawa, Simada, and Tanaka, 1965).

In general, then, it may be pointed out that many of the specific acts of the fetus are induced by stimulation of cutaneous pressure receptors. Mucous membrane reflexes (Minkowski, 1928a) are also probably best thought of as involving receptor mechanisms, so far as pressure is concerned, that are similar to cutaneous reflexes. Preyer (1928) has tabulated the cutaneous responses seen in newborn children. The writer must here again emphasize his belief that, given a stimulus just above the lower threshold and a quiescent fetus in a standard posture, there is typically *one behavior act or reflex* set off by the stimulation of each cutaneous area. These cutaneous "push buttons" are remarkably specific in their behavioral relations when the complexity of the central nervous system is considered.

B Temperature Warmth is one of the skin senses attributed by the philosopher John Locke (1849 edition) to the fetus. In spite of this early sanction it is difficult to understand how marked differences in temperature can normally be present in prenatal life. In the study of the temperature sense in the prematurely delivered infant the matter is further complicated by the great variability of body temperature which characterizes the premature infant (Hess, 1922; Evensen, 1931). Currently accepted views in regard to the mechanism of temperature stimulation start with the assumption that the temperature to which the skin is adapted must be taken as the physiological zero point. From this zero other stimuli are to be considered as above or below, therefore quantified work in regard to temperature in the premature infant is rendered difficult when only absolute temperatures of stimuli are recorded.

Some indications, however, of responses to both warm and cool stimuli in premature infants are given by both Kussmaul (1859) and Genzmer (1882). For the most part these

observations agree with those of the following investigators of the temperature sense of newborn children: Preyer (1882), Canestini (1913), Blanton (1917), and Peiper (1928). These opinions are criticized by Pratt, Nelson, and Sun (1930), who also add their own controlled experimental observations. These three collaborators report that newborn infants react much less strongly to stimuli warmer than the body than to stimuli that are cooler. The writer has described above a study of fetal temperature sensitivity (Carmichael and Lehner, 1937) in which some observations on the temperature responses of guinea pigs were made. In this study unmistakable reactions to temperature both of warm and cool stimuli were obtained under controlled conditions. Drops of blood-warm water call out no response save as they arouse tactile receptors, but cold- or hot-water drops do call out such activities. This sensitivity has appeared by approximately the middle of the gestation period. Here again the "more intense" stimulus (warm or cold) calls out more active responses than the "less intense" stimulus. Thermal homeostasis in the fetus and the newborn does not seem to have been thoroughly studied (Adamsons and Towell, 1965). It has been known for years that body temperatures regulation in the newborn fluctuates more than in the older infant. Premature infants show greater thermal instability than normal-term babies (Miller, Miller, and Westin, 1964; Daniel, Dawes, James, Ross, and Windle, 1966).

C. Pain. Locke (1849 edition) also attributed the experience of pain to the fetus. Since his speculation there has been little direct experimentation upon the fetal pain sense. A number of casual observations show, however, that the application of stimuli that must have caused gross destruction of skin and protoplasm has not called out very pronounced movements on the part of the fetus. Genzmer (1882), on the basis of such observations, holds that the pain sense is very poorly developed in the fetus. On the first day of a premature infant's neonatal life he stimulated it until blood came and got no response. It is certainly true that increase in pressure over that necessary to bring out the typical responses to deep pressure does not always seem in the guinea pig fetus, at any rate, to increase the extent or intensity of re-

sponse. Thus in certain cases the light pressure of a fine hair may lead to extension and stronger pressure of a heavier hair to retraction, but very strong and even obviously destructive stimulation of the same point may or may not make any observable difference in the elicited response over that noted to strong pressure stimulation. Similar observations have been made on the cat fetus (Windle and Giffin, 1931). There can be no doubt that protoplasm-destroying stimuli sometimes bring about violent responses in late fetuses, but even this reaction does not always occur. Speculations on the part played by pain in relation to unpleasantness and discomfort will be referred to in the consideration of the organic senses.

The foregoing paragraphs may be summarized by the statement that there is much evidence that the specialized skin senses have developed to an active functional state long before birth and are able when appropriately stimulated to initiate the release of behavior that is typically very precisely related to the point stimulated.

The Proprioceptive Senses

The neuromuscular spindles may be taken as typical of the many classes of proprioceptors. They are found in the fourth month of fetal life in practically all muscles, including the extrinsic muscles of the tongue and the external eye muscles (Elwyn, 1929). Historically it was not until quite recently that the kinesthetic senses came to be distinguished at all from touch. Carmichael (1926b) has described the history of knowledge concerning the "muscle sense." Much that Bichat (1819) wrote about the active touch of the fetus probably referred to the proprioceptive rather than to the cutaneous sense. Kussmaul (1859) and Genzmer (1882) both refer to responses which must have involved muscle-sense stimulation. Preyer (1885) makes similar references. Peterson and Ramey (1910) also hold that not only touch but also the activity of the muscles of the fetus must lay the foundation "under the threshold of consciousness for a sense of equilibrium and vague spatial relationships." In his study of the relationship between local reflexes and posture, Coghill (1929a) comes to the conclusion that "the limb is able to respond very precisely to stimuli arising within the

body (proprioceptive) as the result of a particular posture before it can respond to stimuli that arise exclusively from the outside world (exteroceptive) "

In experimental work on operatively exposed human and infrahuman fetal material during the active period, the proprioceptive senses are always much in evidence. Indeed, in the responses in fetal rats both Swenson (1926) and Angulo y González (1932a) find evidence of this sense in a 16-day fetus. Coronios (1933) and Windle and Griffin (1931) deal with this sense in detail. (See also Windle, 1940.) As noted in the consideration of the cutaneous senses, these investigators report activities that show that the posture of the cat fetus at the time of stimulation seems in certain cases to determine the response that will be elicited. This point is substantiated by many protocols of the experimental studies of fetal behavior that the present writer has recorded. It is possible that this fact alone may be taken as indicating an early onset of proprioceptive control of behavior.

In this connection one must remember as pointed out above the differential gravitational action on the limb and body in air and in the liquid of the amniotic sac. In one of the studies of a very young human fetus—by Stiassmann (1903), noted above—it is recorded that the observer pressed against, in a manner which apparently means moved, the limb of the fetus. As a result of this stimulation the experimenter could feel the foot press down on his hand. The writer has noticed this same response in young guinea pig fetuses. Even when very gentle or even relatively strong tactual stimulation would not release a response in the forelimb of the fetus, it not infrequently has happened that a forcible movement of the limb itself by the experimenter gave a specific and direct response. As the skin was not anesthetized in the cases reported, this may not of course be thought of as a wholly proprioceptive stimulus, but, as cutaneous stimulation was ineffective in producing the same response, the facts seem to favor the view that the responses noted were proprioceptively aroused. This conclusion must be taken with reservations because the bending and stretching of the skin which result from the bending of a limb are a very strong pressure stimulus.

There is still other evidence that the proprioceptors are effective very early in fetal development. Hooker and Nicholas (1930) have reported experiments on fetal rats in which the spinal cords were completely sectioned at various levels. After some of these experiments it was found that stimulation above or below the sectioned point of the cord might lead to responses in parts of the body innervated by segments of the cord above or below the cut. The question at once arose as to how these impulses were transmitted. As one of the possible explanations of this transmission, these investigators have suggested the following course of events. An exteroceptive stimulus leads to afferent conduction over peripheral nerves to the cord above the region of the section. From this still intact segment of the cord impulses pass out over efferent peripheral nerves to trunk muscles leading to this response. This response mechanically moves the adjoining musculature and thus directly stimulates the proprioceptors in it. These newly activated proprioceptors then initiate afferent impulses which pass into the cord below or above the region of the cut, as the case may be, and thus in turn activate arcs in the intact region of the cord above or below the section, which in turn lead to responses obviously innervated by connections in the cord beyond the section. (See also Hooker, 1911.)

Recent studies of Mavinskaya (1960, 1962) on the correlation of development of skeletal muscle nerve endings with the appearance of motor activity in the human fetus show that primitive sensory and motor nerve endings are present at the 7 to 8 week stage. This is two to three weeks earlier than has previously been reported. Sensory and motor endings arise simultaneously in the muscles studied. Indirect evidence leads Mavinskaya to the conclusion that by the eleventh developmental week these endings are functional. This mechanism, he concludes, is basic in the primary movements of the developing fetus. Such movements are, he believes, reflex in nature. In another area, Laroche (1962) has studied some anatomical aspects of brain development that are important in the growth of behavior.

Windle and Griffin (1931) report many evidences of movement that may be considered on the basis of the analysis of Sher-

ington and his school of reflex physiologists as at least in part proprioceptively innervated. These investigators report that a quiescent embryo held in the cramped condition of the sac will, on the cutting of the sac, sometimes at once assume an exaggeratedly stretched position. It seems as though it were attempting to exercise itself after the close confinement of its entire previous existence. It may be remarked that the writer has seen and photographed similar responses. These maintained "extensor thrusts" are in many respects similar to the tonus of decerebrate rigidity as seen in the adult animal and may possibly involve proprioceptive stimulation. The experiments of Weed (1917), Weed and Langworthy (1926), and Langworthy (1928, 1929) give very clear evidence of other reactions involving this receptor system. The writer has sometimes noted when dealing with a late guinea pig fetus that, if the fetus, still wholly immersed in the bath, is held by its own forepaws on a submerged projection, the animal will seem to try to crawl up onto the projection. Correlated movements are here used which seem, to superficial observation, similar to those employed by a swimmer lifting himself out of the water onto a diving raft. This well-integrated and apparently purposeful activity seems to involve complex proprioceptively directed responses.

Most students of the development of fetal behavior agree that locomotion, as, for example, in the first crawling movements of the fetal opossum considered above, sucking, and breathing are three of the earliest essential behavior systems of the newborn animal. It is interesting to note that each of these in its developed form may involve marked proprioceptive stimulation. The geotopic responses of the opossum fetus considered above, occurring less than 2 weeks after copulation, seem, in the light of Crozier's work (1929) on geotropism in the rodent, to represent a response in which proprioceptive stimulation plays a part. Hunter (1931) has pointed out in a similar study that the vestibular apparatus and other stimulus factors are probably also important in determining such responses.

As noted above, Minkowski (1922, 1928a) reports that there are true tendon reflexes in the early fetus. This is questioned, however,

by Bolaffio and Artom (1924). These latter observers suggest that the responses seen by Minkowski in very early fetuses may have been the result of other forms of stimulation. The mechanism of deep stimulation which they suggest and true tendon-stretch stimulation both involve proprioceptive activity. Indeed, it may be said that the whole study of prenatal behavior in man and in the lower mammals indicates that the proprioceptors in muscles and tendons, and possibly joints, are functional well before birth. By the time of birth these mechanisms have undergone such development that they are among the best-organized receptor fields so far as the initiation and control of behavior are concerned.

The Receptors in the Nonauditory Labyrinth

Adult posture, righting responses, and other reactions to gravity, tonus changes due to rotation, and other alterations of the body in space are often held to result from stimulation of receptors in the nonauditory labyrinth and associated receptor fields (Camis, 1930). As suggested above in a consideration of the development of behavior in the fetal cat, the change of body posture in space has been shown sometimes to involve various combinations of nonauditory labyrinthine, kinesthetic, and exteroceptive stimuli. In the fetus it is peculiarly difficult to isolate the part played by the body exteroceptors and muscle proprioceptors from the part played by the receptors in the nonauditory labyrinth. It should be noted that there is some evidence also that in certain types there is an auditory function subsumed by receptors in this nonauditory receptor complex.

Historically, comparatively little reference has been made to the static senses in connection with fetal mental life as this life was considered in the older speculative child psychology. Some reference, however, has been made to the part played by these receptors in determining the position of the fetus in relation to gravity. Lane (1917) has noted in his study of the development of the senses in the fetal rat considered above that there is an apparent correlation between the histological development of the semicircular canals and the acquisition of postural righting responses on the part of the fetus. In Lane's work, however, no effort to differentiate be-

tween proprioceptive and static stimuli is reported

The development of the labyrinth has been considered by many writers, including Streeter (1906) and Lissell (1929) (Cf also Bowen, 1932, and McCready, Wever, and Bray, 1937) Minkowski (1922), as noted previously, has demonstrated from neurological studies that the labyrinth is fully differentiated in a human fetus of 40 mm. As noted above also, Windle and Griffin (1931) report that in very early cat embryos of 26 or 27 days "rotation of head and trunk appeared to be indefinitely coordinated with the older components, namely, lateral and ventral head and trunk flexion. This activity resulted in motions that strikingly resembled the righting reflexes seen in late fetal life." Windle and Fish (1932) show that in cat fetuses several days before normal birth true labyrinthine reflexes do appear. These reactions make possible what has been called the first "purposeful" movement of the cat, that is, successful locomotion (Windle and Griffin, 1931). This complex behavior act, as already suggested, is held to be a combination of equilibration, body-righting responses, general postural tonus, and rhythmic movement of the limbs.

Coronios and Carmichael have both noticed that, in late cat and guinea pig fetuses, turning the animal over while it is completely immersed in the warm bath does not always lead to righting movements. If the cord is ligated and the same fetus is placed on its side on the experimental table, righting may begin at once. This is possibly to be interpreted as indicating that at this period righting still, at any rate, involves exteroceptive and proprioceptive as well as vestibular functions.

Similarly, Coronios and Carmichael have both been able to elicit typical Magnus reflexes of limb extension as the fetal mammal's neck is turned to the right or the left. These responses are strikingly similar to those of decerebrate mammals and tend to confirm the observation agreed upon by all other investigators that for the most part the young fetus is not under the active control of the cerebral hemispheres. Minkowski (1922) reports labyrinthine reflexes in early human fetuses. He suggests that it is not only possible to elicit responses from general labyrinthine

stimulation but also possible to distinguish between the reflexes attributed by Magnus and his colleagues to the utricle-sacculus complex of receptors as contrasted with those attributed to the complex of semicircular-canal receptors. His analysis leads him to believe that most of the fetal responses to nonauditory labyrinthine stimulation are the result of semicircular-canal receptor action.

Minkowski (1922) states further that in his opinion the early anatomical development and functional use of the vestibular apparatus in the fetus are probably related to the fact that the fetus is living in a fluid medium the specific gravity of which is almost equal to its own specific gravity. Therefore it is almost "weightless," a condition in which he believes the labyrinthine reflexes may be seen to operate to excellent advantage. Minkowski (1928a) is careful, however, not to disregard the possibility that the phenomena noted as the basis for attributing labyrinthine function to the fetus may be the result of the stimulation of proprioceptors in the neck and related receptors. Magnus (1924), in reviewing this work, seems to emphasize the part of the tonic neck reflexes in such activities.

There is some reason to believe that the first eye movements of the fetus are in response to changes of the bodily position of the fetus in space, that is, the first eye movements are occasioned not by retinal stimulation but as part of the general tonus changes of the body brought about by gross movements in space. This fact is brought out very clearly in Kuo's work (1932a). Early eye muscle movements, indeed, may be thought of as specific. These movements take place, however, at the same time that other responses are active and hence may be called part of the "generalized" pattern of responses. Later specific responses are observed which can then be said to differentiate themselves out of the more complex pattern (Minkowski, 1924, 1928a, Tracy, 1926).

There is no reason to believe, however, that these early "postural" responses of the eye muscles are as definitely related to specific aspects of semicircular-canal stimulation as they are in the adult condition so well summarized by Maxwell (1923), Favill (1929), and Holsopple (1929).

Eye movements in adult life that are determined by vestibular function may be modified in various ways (Dodge, 1923). Wellman and Carmichael have made preliminary and as yet unpublished studies of the origin and development of eye movements in the fetal guinea pig. Although these results are still tentative, the following statements may be made, based upon the electrical recording of eye movements in living fetuses.

1 Vestibular stimulation brings about responses before light stimulation is effective in causing eye movements.

2 Optokinetic (that is, light-induced) responses can be called out in the fetal guinea pig which have some of the same characteristics as such responses in older animals.

In these experiments a moving field of bars of light and shade gradients is passed near the eyes of the fetus. The resulting reactions show the slow and fast photic responses typical of such stimuli in adult animals.

It is thus difficult to say with assurance the exact part which the labyrinthine senses play in determining behavior before birth, but it is certain that the tonus adjustments of the body muscles in postural responses, including precise adjustments of eye muscles, are among significant prenatal activities. An understanding of these responses in fetal and adult life is important (Magnus, 1925). One of the points, however, at which a knowledge of the development of proprioceptive responses in the fetus is most important is the evaluation of the studies of postnatal life in which the alleged saltatory character of certain responses there noted is observed in the light of the knowledge of prenatal postural responses. Popularly speaking, the postural actions of the fetus may be considered a fundamental preparation for a diversity of actions in postnatal life. Walking and localizing responses of arms, trunk, and legs can take place only in an organism in which postural mechanisms are developed. It is almost as if these senses provide the essential "gyro-control" necessary before a reaction can be made, just as gyro-apparatus on a warship is necessary if the guns are to be pointed effectively in a heavy sea. In considering the part played by incoming nerve impulses, which themselves result from motor

reactions, one should consider the whole nature of "feedback" systems in biology as related to similar electronic systems (Wiener, 1948).

The Organic Senses

Historically there has been some speculation in regard to the organic senses in the fetus. Some have held that the fetus lives in a perfect world in which hunger, thirst, and all other needs are cared for before they arise (Bichat, 1827). Locke (1849 edition), on the contrary, held at an early period in the total story of speculation about fetal life that the unborn child has "perhaps some faint ideas of hunger and thirst." Kussmaul (1859) agrees with this view. As noted above, Yanase (1907a, 1907b) has studied the movement of the fetal intestines. In the rhythmic nature of these movements is found a basis for possible organic experience and, indeed, for the indirect activation of the skeletal musculature.

The work of Patterson (1914) and Carlson and Ginsburg (1915) on newborn infants and on dogs delivered before normal time indicates something of the nature of the tonus changes of the stomach which may occur in late fetal life. These changes in these organisms are found under appropriate conditions to be rapid and active. This coincides with the observations of Preyer (1893) and of Peterson and Ramey (1910) on the hunger of newborn full-term or even premature infants. Some suggestion of the developmental course of hunger activities and stimulation may be obtained from an observation of Hess (1922) that very early premature fetuses are much less able than later premature infants to show the usual signs of needing to be fed. Jensen (1932) notes the dependence in the infant of the reflex of sucking, a reflex incidentally too often considered merely tactual, on the concomitance of hunger stimuli and tactual stimuli. Preyer (1893) notes the whole sequence of bodily changes, even including those of the eye muscles, which come to be related to the hunger activities of the newborn child.

The theory of "drive" or motivation held by some modern comparative psychologists, which correlates such activities to some extent with organic stimulation, finds support

in the observations of the "random" activity of the fetus which is shown by Liwin (1930) and others to accompany hunger stimuli. As noted above, this activity may not be "random" in the ordinary sense of the word but rather the consecutive or concomitant release of a series already described patterns of behavior (See Carmichael, 1941).

This concept of "drive" is closely related to phenomena considered by certain of the older descriptive psychologists as characterizing the motivating power of the affective processes. That is, "drive" is related to the bodily basis of pleasantness and unpleasantness. Thus Preyer (1882, 1885) and others have discussed reaction related to pleasantness and unpleasantness as apparent before birth or immediately after birth. These conclusions are inferences based on unaided observation of facial expression and on instrumentally recorded bodily changes, such as breathing and directly measured cerebral volume (Canestrini, 1913). Facial expression is reported by Munkowski as beginning in the relatively early weeks of active fetal life, and so it seems that this expressive pattern of so much significance in pleasant and unpleasant situations of later life has had ample opportunity for exercise during the prenatal period.

It may be noted in passing that the rate of fetal heartbeat can be modified by external stimulation, thus possibly leading to vascular stimuli of the sort often considered to fall under the heading of "organic experience." The possibility of respiratory experiences, or "feelings of suffocation," is certainly present, so far as may be judged from a knowledge of stimulation and response. But there is, of course, no evidence that any introspective state actually follows such stimulation.

In conclusion, it may be said that there are possibly certain organic changes in the stomach, intestines, heart, and vascular and respiratory systems that occur before birth which may be important in receptor stimulation. (See Cannon and Rosenblueth, 1937.) It is possible that the stimulation of these receptor systems may lead to fetal activity which does not, of course, have any specific external end in view until, as a result of external stimulation and learning, such stimula-

tion in postnatal life comes to initiate adaptive responses which some wish to characterize as "end-seeking." It may also be noted that no one who has worked with fetal material has failed to see that, after repeated responses, "fatigue" sets in, and for a time stimulation is difficult or impossible (Peiper, 1925).

The question whether fetal quiescence is to be considered as fetal sleep has also been debated (Preyer, 1885). A suggestion has recently been made that there is a "sleep-wake" cycle that is similar in mother and fetus and that this rhythm is carried over into the postnatal period (Payne and Bach, 1965).

This 24-hour clock has been demonstrated to play an important role in the lives of adult animals and men. This mechanism is inborn and is in complete independence of homeostasis as demonstrated by Richter (1967).

Taste. The histological work on the development of the taste mechanism in the embryo is summarized by Keibel and Mall (1910). Taste buds are said by Parker (1922) to begin to appear in man during the third fetal month. The taste receptors are also found to be much more widely distributed in fetal life than in adult life. Parker thus points out that there is evidence of a real retraction of the sensory field in man from the late fetal period to the adult state. At first, taste buds are found on the tonsils, hard palate, and parts of the esophagus. Later, functional taste cells are almost always limited to the tongue (1922). Here is a striking example of a "reflexogenous" or receptor zone which changes as a function of developmental time.

Historically, there have been several different speculative opinions concerning this sense in prenatal life. The early opinions are summarized by Bichat (1827). It is undoubtedly true that the amniotic fluid might serve as a taste stimulus. Since change is ordinarily thought of as essential to real external stimulation, however, the question may be debated as to whether or not the change in the amniotic fluid as pregnancy progresses is enough to make it at any point a taste stimulus (Feldman, 1920). To the writer this seems unlikely. A safe conclusion seems to be that, although the mechanism for

taste is present before birth, there is no adequate stimulation of this sense until after birth. Here again we have an illustration of what the present writer has called the law of *anticipatory morphological maturation*.

Experiments on the sense of taste in newborn children have been carried out by Kussmaul (1859), Genzmer (1882), and Peterson and Ramey (1910) using the method of general observation of facial expression after stimulation. The conclusion of these writers is that sweet is distinguished, even by premature infants, from salt, sour, and bitter. It is difficult to be sure, however, that salt, sour, and bitter are stimuli for behavior that is specific. Canestini (1913) and Jensen (1932) have worked out a method of experimentally recording bodily changes which result from taste. Pratt, Nelson, and Sun (1930) find that under the conditions of their experiment, involving very dilute concentrations, there is not as strong evidence in regard to taste differentiation at birth as had previously been supposed. These later experimenters conclude that the stimulating efficiency of various sapid substances in early life is not only quantitatively but also qualitatively different from the condition in adult life. (See Pfaffman, 1936, in this connection.)

It may thus be said that the receptors for taste are probably never normally activated before birth. The receptor-neuromuscular mechanism, however, has been shown, by work on premature infants, to be ready to function in late fetal life whenever appropriate stimulating conditions are brought to bear upon it. Most experimenters seem to conclude that sweet stands in a class by itself so far as the infant is concerned. Salt, sour, and bitter are apparently distinguishable with greater difficulty. References to the sense of taste in infrahuman fetuses have been given above.

Smell. Bedford and Disse and others quoted by Parker (1922) have considered the embryonic development of the receptor cells of the nervous fibers of the olfactory epithelium. Lane (1917), as already noted, has studied the development of the olfactory structures in the rat. Feldman (1920) points out that the olfactory and tactual parts of the brain were found by Flechsig to be the earliest to be myelinated in the fetus. Historically, save where taste and smell have

been grouped together, there seems to have been general agreement, in the early period at least, that while the nasal cavity is filled with the amniotic liquid there can be no adequate olfactory stimulation. Peyer (1885) specifically defends this conclusion, basing his statement on Weber's assertion (1847) that substances that could be smelled when vaporized were quite unable to arouse the sense of smell when introduced into the nose as liquids.

A great deal of relevant work in this field has been critically summarized by Parker (1922). This work shows that there is excellent reason to believe "that the olfactory organs of an an-inhabiting vertebrate can be stimulated by ordinary solutions, though this form of stimulation cannot be looked upon as normal." Even though this is true, however, the same difficulty as that met with in the sense of taste must be remembered to exist. Even though the amniotic fluid may be an effective inadequate stimulus for the olfactory receptors, there is little reason to suppose that there would be sufficient change in the liquid to effect significant stimulation during prenatal life.

In this sense field, therefore, the study of smell reactions of prematurely delivered infants will again be very significant in any determination of how the functional development of the olfactory mechanism progresses during late fetal life. Kussmaul (1859) found that asafetida and certain other odors, but not irritating substances, led to responses in a 1-month premature infant. He is not sure that he was able to secure responses in earlier premature infants. Peterson and Ramey (1910) also found smell reactions in premature infants.

Historically, there has long been a belief that the newborn child could distinguish odors effectively. Feldman (1920) asserts that the Jewish sages in the time of the Talmud believed that a blind baby could tell his mother's milk by smell and taste. Rousseau also commented on the sense of smell in newborn infants. (Feldman, 1920.) Peyer (1882) reports that an 18-day infant refused a breast nipple on which kerosene had been placed but eagerly took the other odorless breast immediately after the refusal. Peyer (1882) also demonstrated that newborn guinea pigs apparently select their food by

the sense of smell. He asserted, moreover, that in young animals, including man, the sense of smell in general is most important in determining behavior. Indeed, in infrahuman animals it is suggested that this significant aspect of behavior determination by smell does not come to be neglected to the extent that it is by civilized man.

Experimental work on the sense of smell in newborn infants, which is probably also generally applicable to late premature infants, has been summarized by Canestini (1913), Peiper (1928), and Pratt, Nelson, and Sun (1930). Canestini concludes that there has been some exaggeration in regard to the effectiveness of the sense of smell in young animals. He feels that most of the work on smell has been concerned with stimuli which act on the receptors related to the trigeminal cranial nerve components of the nasal receptor surfaces. These trigeminal components are probably best considered as the "common chemical sense" (Parke, 1922) and not in the usual sense of the term "tactile" as suggested by Pratt, Nelson, and Sun (1930). Certainly the trigeminal endings are not "olfactory" in the ordinary sense. Stimulation of the common chemical sense receptors typically sets off violent reactions, such as sneezing. A characteristic irritant of this sort is ammonia. It is significant in this connection to notice that Pratt, Nelson, and Sun found ammonia to be a peculiarly effective "smell" stimulus. Probably the responses of a newborn infant to ammonia should be considered as responses to the common chemical sense rather than to true olfactory stimulation.

In summary. The neural mechanism for olfaction—that is, the mechanism related to the so-called first cranial nerve—is developed before birth, and the possibility of inadequate stimulation exists before birth. It is probably true, however, that olfaction does not generally occur in its normal form until the nasal cavity comes to be filled with air. Premature infants, at least in the last month, are able to smell substances when air enters the olfactory cavity. Much work on smell, however, has probably been vitiated by the fact that the free nerve endings of the trigeminal nerve (the fifth cranial nerve), the receptors for the common chemical sense, have been stimulated rather than the true olfactory spindles.

Hearing. Anatomically the development of the ear in the individual has been extensively studied. This work is summarized by Keibel and Mall (1910). Hess (1922) shows an original drawing of a section through the ear of a late fetus. Stevens and Davis (1938) have summarized much of the experimental work upon the adult auditory mechanism.

Historical opinion on the sense of hearing in the human fetus is probably best summarized in the words of Kussmaul (1859): "Von allen Sinnen schlummert das Gehör am tiefsten." The history of experiment on the sound response of full-term and prematurely born infants is excellently summarized by Pratt, Nelson, and Sun (1930). The general conclusion of these authors is in harmony with that of the later investigators, that hearing becomes effective only in the very early part of postnatal life.

Most of the early investigators of the development of audition concluded that the auditory mechanism was developed to a point at which it could be functional before birth but that the infant remained deaf until by breathing, crying, and possibly yawning the Eustachian tube was opened. Only in this way, they suggested, could the somewhat gelatinous liquid of the fetal middle ear be drained out (Peyer, 1882). Peterson and Ramey (1910) specifically secured evidence of auditory response in a prematurely delivered infant as soon as there had been an opportunity for the draining of the middle ear. More modern work seems to have offered no reason to differ with this conclusion so far as stimuli of normal intensity are concerned. Peyer (1882) also reports that newborn guinea pigs are deaf for $\frac{1}{2}$ hour after birth and are then sensitive to tonal stimuli of a great variety of frequencies (C of third octave to E of eighth). Avery (1928) has secured comparable results on late guinea pig fetuses prematurely delivered, as noted above. The experiment of Rawdon-Smith, Carmichael, and Wellman (1938), which shows by electrical methods of recording the onset of functional activity in the cochlea, has already been referred to. This experiment shows that the guinea pig fetus can hear before birth, judging by both electrical and behavioral criteria.

Although there has been some speculation

on the fact that the sounds inside the mother's body might act as sound stimuli to the fetus, little evidence has been brought forward to make this seem certain (Freyer, 1885). There are experimental findings which suggest that loud auditory stimuli may activate the human fetus. Peiper (1925) was led to this study because he noted that in six neonates, very soon after birth, changes in the breathing curve were found in response to a special sound stimulus. The change in the breathing curve is reported as marked. He therefore decided to try to find out whether or not any indication of hearing before birth could be secured. It had been discovered that auditory and other sudden stimuli give two sorts of responses in the newborn—one, a change in breathing rhythm, and the second, a change in the level of general movements. Peiper felt that there was no sure reason to believe that the unborn child would respond differently if it could be stimulated in its auditory receptors. The breathing center in the brain is open to stimulation before birth. He therefore thought of the possibility of using the prenatal "breathing movements" of Ahlfeld as an indicator of sound response. The disadvantage was found, however, that these movements were not always present, and so the number of subjects was limited. But with proper recording apparatus he was able to take records of the general movement of the fetus through the body wall of the mother.

It was obvious that sounds would be much muffled on their way to the fetus. Therefore a very loud sound was chosen as a stimulus, an automobile horn being used. The experimenter waited until the fetus was absolutely quiet and the mother had been prepared so that she would not herself respond to the stimulus. Incidentally, it proved impossible to train all mothers in this way. The stimulus was given in a quiescent interval. In more than a third of the subjects studied, definite fetal reactions were secured to stimulation of this sort. There were, however, individual differences in responsiveness. Sometimes the response was given on one day and not on the next. The movements which the fetus made in response to the stimuli also showed individual differences. Most often, however, the fetus seemed to draw its whole body together. Peiper (1925) comments that it

might seem to one who had not been present at the experiments that the movement was a response of the mother and not of the fetus. He is certain, however, that one who had actually observed the experiment would be convinced that the response was fetal and not maternal. As an additional safeguard, a pneumograph was placed on the mother's chest and her breathing curve taken during the experiment. After a good deal of practice it was possible to train some mothers so that they made practically no response, and thus the fetal response could be recorded. Continued stimulation led to a diminution of the effect. This corresponds to a frequently observed phenomenon of fetuses and neonates: their responses are easily fatigued or exhausted. Peiper even goes so far as to suggest that this change in response may be thought of as a simple kind of attention. He also states that one mother remarked that she had noticed definite movements of the fetus while attending a concert.

Forbes and Forbes (1927) have reported a case of apparent fetal hearing. Thirty-one days before her baby was born a pregnant woman was lying in a metal bathtub full of warm water. A 2-year-old child was playing on the floor beside the tub. Accidentally the child struck the side of the tub with a small glass jar, and at once a sudden jump of the fetus was felt by the mother, which gave a sensation quite unlike the usual kicks or limb movements. A few days later an observer struck the side of the tub below the water line a quick rap with a small metallic object, meanwhile watching the mother's abdomen. A fraction of a second after the rap, a single quick rise of the anterior abdominal wall was clearly visible. The mother at this moment felt the same jump inside her abdomen as previously reported. Her own muscles were entirely relaxed, and she was not at all startled by the noise, nor was she conscious of perceiving any vibration through the skin. The mother's tactual sense later tested showed that the same intensity of vibration could be perceived only by those portions of the skin coming in contact with the tub. In the infant in question, 8 days after birth, it is interesting to note that while the baby was nursing an auditory stimulus occurred which resulted in the flattening of the baby's

ear against the side of the head for a few seconds, after which the ear relaxed again. These same investigators also report another case in which concerts attended toward the end of pregnancy resulted in troublesome activity on the part of the fetus. The conclusion of these writers (1927) is

Good evidence exists that the human fetus 4 or 5 weeks before birth can respond with sudden movements to a loud sound originating outside the body of the mother. It seems probable that this is a true auditory-muscular reflex but the possibility of reception through tactile organs in the skin cannot be excluded.

Recently the fetal heart rhythms of 32 pregnant women in the latter part of pregnancy were studied. Tones of 1000 and 2000 cycles per second of an intensity of 100 decibels were given for 5 seconds. Acceleration of fetal heart to the 1000 cycles per second tone averaged 7 beats a minute. To the 2000 cycles per second tone the increase was 11 beats a minute. The mother's heart did not show any acceleration. The hearing of premature infants has been studied by a similar technique (Johansson, Wedenborg, and Westin, 1964).

The response of the fetus to auditory stimulation has been made the basis of several studies of fetal learning, to which reference is made below.

In summary. It may be said that the auditory mechanism seems to be well developed structurally during later fetal life, but in general, possibly because of the closure of the external ear or because of the gelatinous liquid which fills the middle ear, the fetus is probably deaf to sounds of normal intensity before birth and during a short period immediately after birth. Strong sounds, however, especially those which can directly pass through the mechanical blocks noted, seem to be able to bring about auditory stimulation before birth, although it is still possible that such responses are tactual rather than truly auditory.

Vision. The specific morphological cellular changes which are the essential antecedents to the development of the function of the human eye begin in the second or third week of development of the embryonic period, and from that time on an elaborate

series of events occurs until, in the normal human individual, binocular convergence and the diverse activities associated with visual space perception and stereoperception develop in the young child. The anatomical aspects of this growth have been summarized by Keibel and Mall (1910) and by Mann (1928). Hess (1922) has described in some detail the eye of an early premature infant.

So far as the function of sight in normal prenatal life is concerned, there has been general agreement that the absence of radiation of the sort that typically activates the retina makes true sight all but impossible in prenatal life (Peyer, 1885). The possibility does exist that under very strong light stimulation, if the head were in just the right place, radiation falling on the mother's abdomen might stimulate the fetal retina, but this seems most unlikely. There is evidence, however, given by Kussmaul (1859), that pronounced differences between light and dark bring about specific reactions in an infant born 2 months before term. Peterson and Ramey (1910) also found light reactions in premature infants. Genzmer (1882) does not confirm this observation. Peyer (1885) agrees that adequate stimuli are impossible during fetal life, but he considers the possibility that inadequate stimuli of pressure similar to the stimuli which bring about phosphenes might be effective in prenatal life.

There is evidence that even at normal birth the optic nerve and related structures have not fully developed anatomically (Pratt, Nelson, and Sun, 1930). This knowledge has led to speculation in regard to the neural basis of the development of eye muscle function in neonatal life. This whole question has been considered by Peyer (1882) in relation to the nativistic and empiristic theories of the visual spatial world, with the conclusion that the evidence is conflicting.

The writer has taken a few records of the eye movements of human babies, using the electrical recording method. These movements were induced by placing the baby's head in a large rotating drum on which there were striations. The results of these experiments showed that it was possible to elicit optokinetic nystagmus in early infants. This technique may also be used as an objective

means of determining lower brightness and color vision thresholds in normal or premature newborn infants. For a description of this technique especially as applied to recording of eye wink and eyeball movements see Carmichael and Dearborn (1947).

One of the best indices of the sensitivity of the fetus to light, although possibly not to the full neural mechanism involved in true visual responses, is thought to be the onset of the light-stimulated pupillary reflex. Portal (1818) alleged that responses of the iris diaphragm did not appear during fetal life. Hess (1922) and others, however, have shown that in premature infants strong light stimulus leads to contraction of the pupil, followed in 2 or 3 seconds by dilation again. Bolaffio and Aitom (1924) and Minkowski (1928a), as noted above, have been unable to make unequivocal statements about light reflexes in late fetuses. As pointed out in another part of this chapter, care must be exercised, especially when strong light is used, not to confuse the independent, non-neurally determined muscular response of the iris to light with the true iris reflex. The development of the pupillary response in postnatal life has been summarized by Perper (1928).

Much of the evidence in regard to the general muscular movements of the eyes in the first days of life has been summarized by Piatt, Nelson, and Sun (1930). Early eye movements have been carefully studied in the newborn child by Sherman and Sherman (1925). As already noted above, however, there is excellent evidence to show that during fetal life eye movements occur as part of the general tonus change of the body musculature resulting from the spatial reorientation of the entire fetal body. (See Carmichael, 1940b.) Preyer (1882) and many students since his time have discussed the development of function in the auxiliary musculature of the eye, including the mechanism of winking. In general, great differences are noted in the tonus and general behavior of the lids in the newborn child as contrasted with those of the older child. Some hints of the beginning of this development are to be found in the reports on fetal development given by Minkowski. In a fetus of only 160 mm he found that touching the

closed eyelid led to a contraction of the orbicularis muscle (1922).
